ALCOHOLIC FERMENTATION.

Manual of Alcoholic Fermentation and the Allied Industries. By Charles G. Matthews, F.I.C., F.C.S., &c. Pp. xv + 295. (London: Edward Arnold, 1902.) Price 7*s.* 6*d.* net.

MR. MATTHEWS has written an eminently readable book, containing a large amount of useful information. The work is divided into twelve chapters, to which eight appendices are added; it is prefixed by a good and thorough table of contents and finishes with a capital index.

The first chapter deals with "Alcoholic Fermentation. General Considerations leading to Special Ones." In this chapter we have an account of the earlier work of Leuwenhoek, Fabroni, Gay-Lussac, Cagniard de Latour, Schwan, Turpin, &c., and the theories held by Liebig, Fremy and Traube. The work of Reess and of Pasteur receives due acknowledgment, and towards the end of the chapter we find a summary of the various views which have been held with regard to fermentation.

"(1) Fermentation as an effect resulting from the growth or vegetation of an organism. (The accepted theory as established by scientific knowledge.)

"(2) A mechanical theory or theory of chemical decomposition. (Liebig's theory, and that of the Liebig school.)

"(3) A theory of so-called catalytic action or decomposition by contact—presumably of the ferment and fermentable substance. (An elegant mode of expressing ignorance of the true action.)"

The last remark in brackets appears somewhat hard on members of the catalytic school, and the following statement,

"that apart from the results of the vital processes of the yeast organism or other living cells, the production of alcohol from a saccharine liquid is unknown" (p. 8),

seems scarcely justifiable in the light of Buchner's researches. In fact, the references to Buchner's work on pp. 47 and 121–122 show that the author quite accepts the fact that fermentation may take place in the absence of cells, and is in any case due to an enzyme. "Contact" reactions undoubtedly take place amongst organic as well as inorganic compounds, and really the term "catalytic" is very useful. It would, however, be unfair not to acknowledge that such discrepancies have been observed between the courses followed, on the one hand, during the hydrolysis of esters by mineral acids and, on the other, fermentation by yeast as to lead to the idea that the two processes are fundamentally different. The recent work of Adrian Brown on "enzyme action" (*Chem. Soc. Trans.*, lxxxi. 373), and of Horace Brown and Glendinning on the "hydrolysis of starch by diastase" (*ibid.*, p. 388) prove clearly, however, that enzymes working in dilute solutions (*i.e.* when not overloaded) follow the law of mass action, so that one must conclude that processes of this nature are fundamentally as mechanical as the inversion of cane sugar by a mineral acid.

Chapter ii. deals chiefly with the morphology of yeast, whilst chapter iii., on the "Saccharomycetes and other Organisms acting as Alcoholic Ferments," gives a clear and full account of the various species of yeast which have been identified, the chapter ending with an account of *mycoderma vini*, *mucor racemosus*, &c., and the conditions under which they can behave as alcoholic ferments. Chapter iv., on "The Effect of Physical and Chemical Influences on the Yeast Organism," deals with the food material of yeast, the heat developed during fermentation, and the *optimum* temperature, and naturally leads to a further consideration of theories which have been put forward as to the fermentative action of yeast and to mention of Buchner's *zymase*. Referring to this, the author justly remarks

"that though it pushes the cause of alcoholic fermentation a little further back, there is no reason to believe that Buchner's zymase could be produced by other than vital agencies or in association with living matter."

This does not, however, preclude zymase from acting in a mechanical manner, neither is it *proved* that some inorganic ferment might not have somewhat the same effect, however improbable this appears in the light of present knowledge.

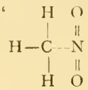
Chapter v., entitled "Chemical Science," one cannot

help thinking would have been better left out. To attempt to cover the range of chemical science from atoms and molecules to the elements of organic chemistry in so short a space is practically impossible, nor should it be necessary in a technical work.

Moreover, if such matter appears to the author desirable, he should take especial pains to be accurate. Chemists will take exception to N_2O_2 as the formula of nitric oxide, also to the triad radical $(CH)'''$ being called *formyl.*

The footnote to p. 75 is not quite clear, whilst p. 76 contains the following :—

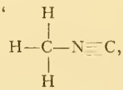
"



(nitromethane or methyl nitrite)"

and

"



belonging to the class called cyanoparaffins." On p. 78 we are informed that

"ethers are a class of compounds bearing the same relation to the alcohols that the metallic oxides do to their hydrates."

"The Carbohydrates" are described in chapter vi., and the author deals in succession with the pentoses and hexoses, passing on to the di-, tri- and poly-saccharides. The subject of the starches occupies several pages and is illustrated by well-executed plates. In considering the question of yeasts, no one can fail to be struck with the influence the scientific work of Pasteur, Hansen and others has had on the fermentation industries, and chapter vi. perhaps brings home to the reader even more forcibly the powerful effect the brewing industry has had in promoting the scientific examination of the carbohydrates.

"Nitrogenous Substances and the Nutrition of Yeast" form the subject-matter of the next chapter, and albumenoids, amido-substances and enzymes are described in succession. A few misprints have occurred amongst the formulæ of the amido-acids, *e.g.* amido-acetic acid, glutamine and tyrosine. Generally the chapter is clear and interesting; the author has no need to apologise for the space devoted to the topic.

With chapter viii. we come to the first practical application of fermentation, and in eighteen pages we are made acquainted with the chief features in the manufacture of wine, including cider and perry. But it is in the succeeding two chapters (ix. and x.) that the author is really in his element, and devotes upwards of fifty pages to the science and practice of brewing. Chapter ix. is occupied with malting and the physiological and chemical changes involved; the next chapter leads us by all the intermediate stages from the mash-tun to the barrel, and gives much information on the influence of the composition of brewery waters and the courses of different fermentations.

Chapter xi. deals with "Fermentation from the Distiller's Point of View," and is all too short (twenty-seven pages) to give anything like a complete account of this extensive and important industry. The author confines himself to the manufacture of pot-still whisky and "patent-still spirit." With regard to the former, practice varies so largely that the description given must not be taken as typical of the working of *all* malt distilleries. One may note the temperature at which the "sparge" is applied; 170° is frequently exceeded, and the use of stirrers in wash stills by no means universal, especially where small stills are employed. "Maturation," according to the author, takes place

"chiefly by a selective absorption which the wood of the cask exercises, and also by some little oxidation and etherification of the higher alcohols";

certainly a more definite and rational view than that which supposes new whisky to contain objectionable substances which, as the reviewer has sometimes been assured, break up into substances communicating a fine flavour to old spirit.

The manufacture of patent still spirit as carried out in this country is next described, and we then pass on to continental processes. German methods deservedly receive a large amount of attention, and the author draws particular attention to the preparation of the "Vormaisch" by sowing vigorous yeast in a strong wort, slightly acidified by a small lactic fermentation and subsequently sterilised. The ripe "Hefegut" so obtained is used for pitching the chief mash; the effect of the small quantity of lactic acid is not only favourable to the yeast, but restricts the growth of bacteria. Mr. Matthews mentions the fact that artificial acidification has been frequently resorted to; the subject has been recently ventilated by Dr. Lange before the Verein der Spiritus-Fabrikanten. Dr. Lange states that hydrochloric acid at first gives excellent results; unfortunately, the bacteria soon become accustomed to it, as they also probably would to sulphuric acid. Butyric acid appears to be efficient if properly handled, the yeast remaining cleaner.

The course of fermentation is illustrated by diagrams taken from Märcker's "Spiritusfabrikation." One wishes that this work had also been drawn upon for diagrams of recent German distillery plant, Ilge's automaton, for example.

The last chapter (xii.) deals with the cultivation of pure yeast and the brewing of "lager-beer," the comparative uselessness, and perhaps harmfulness, of endeavouring to brew English beers with pure cultivations being well brought out in the last few pages.

The eight appendices are chiefly concerned with laboratory instructions; D, E and F are, however, of more general interest, since they deal respectively with conjugating yeast, the nutrition of yeast, and the combined action of diastase and yeast on starch granules.

Mr. Matthews is to be congratulated on the way in which he has treated his subject, but the reviewer cannot help thinking that if he gave the space devoted to matters of general chemical knowledge to the subjects of wine and the preparation of the purer forms of alcohol, the book would gain in usefulness. J. T. H.

THE GEOGRAPHY AND GEOLOGY OF CELEBES.

Materialen zur Naturgeschichte der Insel Celebes, Band iv.—*Entwurf einer geographisch-geologischen Beschreibung der Insel Celebes.* By Dr. Paul Sarasin and Dr. Fritz Sarasin. Pp. xi + 344 + 28; 13 plates. (Wiesbaden: Kreidel, 1901.) Price Mk. 50.

THIS, the fourth volume of the series which the authors have devoted to the natural history of Celebes, is a welcome addition to our knowledge of the East Indian Archipelago. The recent geological history of the island, and the light thrown upon it by the distribution of the animals and plants of the region, has already formed the subject of a special memoir. Here we have a description of the surface features and configuration of Celebes so far as that has been explored, a record of many interesting observations, geographical and geological, made during several years spent in travel in nearly every quarter of the island, with petrographical notes on the rock specimens collected (including a special chapter by Prof. C. Schmidt), a sketch map on the scale of 1 in 2,000,000 and tables of the observed altitudes of many important stations.

The outline of the island, sinuous and branching, is the external expression of its geological structure. A folded mountain chain, of which some peaks rise to 5000 or 6000 feet above the sea, forms the axis or backbone of Celebes. It is not simple, but consists of several parallel ranges, more or less intermittent, with longitudinal valleys between them. These valleys appear to be synclinal or to be due in some cases to depression between parallel lines of fault which trend with the folds. Not much is known about the mountainous interior of the island, but from the specimens of rocks collected, which include granite, gneiss, mica schist, chlorite schist, epidote glaucophane schist, quartzite and crystalline limestones, it is certain that there is a large development of metamorphic rocks. No fossils have been obtained from this series, but the authors believe that some of the crystalline limestones may be of Jurassic age.

This axis of metamorphic rocks is bent almost at a right-angle where it crosses the equator, and in the interior of the bend another less important series of folds runs roughly parallel to the main external ridge which forms the dominant structural feature of the island. A striking peculiarity of the surface configuration is the presence in each system of folds of a longitudinal depression flanked on each side by ridge-like elevations. This central valley runs from end to end of Celebes. It largely determines the direction of the drainage, as the principal interior streams run in it for long distances, parallel to the shores, till they take advantage sooner or later of one of the breaks in the continuity of the hill ranges to pass outwards to the sea.

The narrow and not very well defined coastal plain consists, for the most part, of Tertiary and later deposits very frequently intercalated with volcanic rocks. The Eocene is well represented by massive nummulitic and orbitoidal limestones, often coralline. Beneath these there are sometimes exposures of sandstone, and not uncommonly radiolarian clays and cherty beds which may be lower Eocene or possibly Cretaceous. Overlying the Eocene are sandstones and conglomerates known as the "Celebes Taveyannaz beds" (from their similarity to the Taveyannaz group in the Alps) and an extensive "Celebes Molasse," with fresh water, brackish water, marine and land fossils. Pliocene shell beds and Pleistocene strata are well developed in the lower grounds and along the shores. The Tertiary geological history of Celebes is outlined as follows:—The Eocene began with deep-water conditions (radiolarian clays) followed by shallow coral seas. In the Miocene the great upheaval took place and the mountain axis attained its complete development. This was an epoch of land conditions, and was accompanied by the deposit of the "Celebes Molasse." During the Pliocene the land area was much greater than at present, but in the Pleistocene depression ensued, and is regarded as having been at least 300 feet. Thereafter minor oscillations have taken place; a well-marked raised beach can be traced at heights of 90 feet above the sea-level indicating recent elevation, while in other places submerged forests point to slight and local depression.

Over most of the island signs of volcanic activity abound. One crater named Una Una was in eruption in 1898, but there are few historic records of volcanic outbursts, though many may be traced in the traditions of the natives. In the extreme south the great peak of Bantaeng (2970 m.), an Etna covered with parasitic cones, is a well-known object and has already been described by several travellers. The authors ascended it, and give a map of the higher parts of the mountain. This map shows a very large breached crater occupying the summit and accompanied by two enormous depressions (presumably also craters) to the south of the principal one. Beds of ash and lava flows are very frequently interbedded with the Tertiary strata, and in the Minahassa region at the north-east termination of the island there is a cluster of volcanic mountains, some of which must have been very recently in eruption, while others are in various stages of denudation and decay. This is one of the most interesting parts of Celebes, and some of the best chapters of the book are those devoted to the description of these volcanic cones and craters. For the excellent photographic illustrations which accompany them there can be nothing but praise.

The volcanic activity appears to have first manifested itself in the Miocene, and to have followed the era of folding and upheaval. Many types of effusive rocks are found. The commonest are apparently andesites (propylites) and basalts. But leucite-tephrites, trachytes and phonolites were also emitted, and Prof. Schmidt has furnished descriptions of some very fine nepheline-bearing shonkinites which appear to be the plutonic representatives of this group. They are accompanied by bostonites and gauteites as dyke rocks. In the volcanic areas hot springs are numerous, and some of the quartz veins are auriferous. Some interesting notes are also given on the configuration of volcanic bombs.

A special feature of the geography of Celebes which has attracted a good deal of attention is the existence of inland lakes of considerable size. These are found in the central valley depressions between the hill ranges, and they occur in well-defined chains in these valleys. The largest is the Towuti Lake, but Lake Posso and

Lake Tempe are also considerable sheets of water. Their great depth is notable; Lake Posso is 160 fathoms deep, Lake Motana 260 fathoms. The authors believe that they are of tectonic origin and are due to depression in the synclines between the mountain uplifts. They may be flanked by lines of fault, and the very steep slopes of their shores, as shown by the soundings, is easily explained on this hypothesis. Their resemblance to the Central African lakes is close and is heightened by the presence in them of a molluscan fauna the affinities of which are said to be Miocene. Their great depth would appear to be against their Miocene origin, but as the areas that drain into them are small, it may well be that the deposition of sediment is too slow to have produced any very great effects. It is suggested that depression has also taken place and has counterbalanced the accumulation of alluvial material brought down by the streams.

In conclusion, it may be noted that the work contains a full bibliography of the geology and geography of Celebes, and the description of each district is accompanied by a synopsis of the observations of previous travellers.

OUR BOOK SHELF.

More Tales of the Birds. By W. W. Fowler. Pp. 232; illustrated. (London: Macmillan and Co., Ltd.) Price 3*s.* 6*d.*

THIS is a delightful little book of stories, admirably written and beautifully illustrated, in which birds play a more or less important part. It is in no way one of the numerous works on the popular natural history of birds with which the market is nowadays flooded, but strikes a line peculiarly its own. In the first chapter we have a pathetic story of a young soldier whose thoughts were turned to home and its associations during the Waterloo campaign by a lark's nest which escaped destruction although situated in the midst of the great battle-field. The second deals with the toils and troubles of a house-martin, as supposed to be narrated by the bird itself. In regard to the reason for the annual migration, the bird is made to say: "We always do come here, and our ancestors always came, so I suppose we shall go on doing it. Besides, this is really our home. We were born here, you see; and when the heat begins in South Africa there comes a terrible feeling in our hearts, a terrible home-sickness, and we *must* go." Evidently, so far as birds are concerned, the author does not believe in the theory that Africa was a great centre of animal evolution.

Jackdaws, magpies and starlings severally form the texts for other chapters. To ornithologists, perhaps, the interest of the book will centre on the exquisite illustrations, by the accomplished pencil of Miss F. L. Fuller, which are alone worth the price charged. Although there are some to whom this class of writing does not appeal, many readers of all ages and both sexes will doubtless find pleasant occupation for a spare hour or two in this bright and entertaining little volume. R. L.

College Algebra. By L. E. Dickson, Ph.D. Pp. viii + 214. (New York: Wiley and Sons. London: Chapman and Hall, Ltd., 1902.)

THE usual profession of "rigour" is followed here by the usual inaccuracies. On page vii. we are told that = means "equal"; on p. 69 it is stated without proof that if r is a proper fraction the limit of r^n is zero when n increases indefinitely; the discussion of the exponential theorem in art. 129 is thoroughly unsound, and the proof that every equation has a root (pp. 211–12) is marred by serious defects. On the other hand, the chapters on logarithms, mathematical induction and theory of equations are good. Probably this book has been written rather hastily; otherwise it is difficult to understand how such a competent mathematician as the author is known to be should have overlooked so many deficiencies. Even in the chapter on the binomial theorem for any index, he calmly applies the rule for multiplying two power-series without discussing its validity either there or in any other passage of the book! Finally, Mr. Charles Smith is made responsible for the assertion that the binomial expansion of $(1+x)^n$ converges for $x=1$ if $n<-1$. Very likely this is an uncorrected misprint for $n>-1$; but why refer to Mr. Smith instead of to Abel's classical memoir? M.

A Laboratory Manual of Physics. By H. Crew, Ph.D. and R. R. Tatnall, Ph.D. Pp. xii + 230. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1902.) Price 5*s.*

EACH exercise commences with references to certain school text-books, but, unfortunately for the British reader, these are all American works, and, so far as the reviewer knows, they are not used in any schools here. We are amused to find that metre scales are called metre "sticks" in the States. There is a good simple chapter on inertia, and a form of inertia balance is described. It seems to us a mistake to omit all experiments on velocity and acceleration because of their difficulty. Friction occurs in all real machines, and it ought to be studied in elementary works. The apparatus is generally of quite a simple character and very suitable for school use. Appendix A contains an extract from one of Boyle's papers in which he describes an instrument virtually the same as Nicholson's hydrometer, and the authors call attention to this in their description of that instrument. The book will prove very useful in conjunction with the text-books to which references are made. S. S.

Photographic Apparatus. Making and Repairing. By F. W. Cooper, D. W. Gawn and others. Edited by E. Brown. Pp. xvi + 128. (London: Dawbarn and Ward, Ltd., 1902.) Price 1*s.*

IT is not every photographer who wishes to make or repair his own apparatus, but those who are acquainted with the use of tools will find this small book a useful help if they require it in aiding them to fit up all kinds of convenient accessories to the photographic camera and dark room. The information given is concise and the instructions are clear; and numerous illustrations, 180 in number, are included which materially aid the text from a beginner's point of view. The ground covered is by no means meagre, for the worker is made acquainted with such subjects as the studio and studio fitments, the dark room and its fixtures, cameras and accessories, printing and enlarging apparatus, concluding with numerous and useful miscellaneous attachments. That the instructions are the result of practice is shown by the numerous writers on the varied subjects, most of the information being reprinted with additions from articles in *The Photogram.*

Monographie der Gattung Alectorolophus. Von Dr. Jakob von Sterneck (Trautenau). (*Abhandlungen* der k.k. zool.-botan. Gesellschaft in Wien, Band i., Heft 2, October 31, 1901.) Pp. 150. (Wien: Holder.)

AN exhaustive monograph of a genus of plants, variously known under the names of Fistularia, L., Rhinanthus, L., Alectorolophus (Haller), Allioni, and Mimulus, Scopoli. Fifty-one species and two hybrids are described by the author. The genus is most numerous in Europe (a familiar British representative being a common meadow-plant, known as the Yellow Rattle); but it also extends throughout a considerable portion of temperate Asia and North

America. The species are divided into six sections, and the synonymy, variation, distribution, &c., of each species are given in great detail, at least in the case of well-known species. The probable evolution and phylogeny of the genus are also discussed, and to the latter subject the elaborate "Stammbaum" is devoted. The three maps show the distribution of various species of the genus. Scientific botanists should find much to interest them in Dr. Sterneck's work

A Text-book of Insanity. By Charles Mercier. Pp. xiv + 222. (London: Swan Sonnenschein and Co., Ltd., 1902.) Price 6*s*. net.

MR. MERCIER addresses his little work directly to the ordinary medical student, for whom, it appears from the preface, there has hitherto been no text-book of insanity of moderate compass. For the practical student so clear and brief a description of the leading types of mental disorder from the pen of a recognised authority will be of high value. The work has also its merits from the standpoint of the theoretical psychologist, though he will probably prefer to study the author's views in his larger work, "Psychology Normal and Morbid." The account of normal mental activities by which the description of insane deviations from the normal is preceded is eminently clear and judicious. The psychologist should also be thankful to the author for discarding the bewildering nomenclature of *manias* and *phobias*, and offering a simple and intelligible classification of mental diseases, based on the distinction between forms of insanity (*i.e.* the aggregate symptoms presented simultaneously at any stage by a patient) and varieties of insanity (*i.e.* specific types of the course run by a case from first to last). Besides purely medical and psychological information, the book contains some useful remarks on the legal responsibilities of the practitioner in connection with insane patients. A. E. T.

Leçons sur les Séries à termes positifs. Par Émile Borel. Recueillies et rédigées par Robert d'Adhémar. Pp. viii + 94. (Paris: Gauthier-Villars, 1902.) Price fr. 3·50.

THIS appears as the third instalment of Prof. Borel's lectures on the theory of functions. It is somewhat more fragmentary than its predecessors, and has, in fact, the typical qualities and defects of a set of lecture-notes. As an introduction to the memoirs of Hadamard, Mittag-Leffler and Poincaré, as well as to those of Prof. Borel himself, these chapters will be very serviceable. Perhaps the most noteworthy articles are those which deal with the theory of increment (*croissance*); it is there shown that there is no natural scale of orders of magnitude. In fact, an aggregate of orders of increasing functions can be constructed which is not numerable. Moreover, functions have been invented which have no regular order of increase; thus an example is given of a function which is comparable with $\exp x$ for an infinite number of values of the variable, and with $\exp(\exp x)$ for another infinite number of values. This will cause searchings of heart in certain quarters, no doubt; even Prof. Borel remarks that "fort heureusement, les fonctions qui se présentent *naturellement* aux géomètres sont, en général, de nature plus simple."

Practical Exercises in Magnetism and Electricity. By H. E. Hadley, B.Sc. Pp. xii + 232. (London: Macmillan and Co., Ltd., 1901.) Price 2*s*. 6*d*.

THIS is an excellent collection of laboratory experiments, suitable for the higher classes in secondary and public schools. Magnetism is taken first, then electrostatics and current electricity. An appendix gives some instruction for making the necessary apparatus. The author wisely confines the experiments to those which can be performed with quite simple apparatus.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Remarkable Lunar Halo.

ON the night of January 19 of this year a singular lunar phenomenon was visible here. The sky had clouded over and was covered with a nearly uniform whitish sheeting of cloud, through which the brighter stars could be seen. There was no wind. The barometer stood at 29·20 inches and the temperature was 28° F. The moon, which was near the meridian, was ten and a quarter days old and had a north declination of 19°.

Surrounding the moon was the ordinary lunar halo of 45° or 50° in diameter, which is so often seen at the approach of bad weather. This ring was clearly defined on its inner edge, which was of a reddish or brownish colour; it rapidly diffused on its outer edge and was perhaps a couple of degrees in thickness. The whole interior of the ring was darker than the sky outside of it anywhere, which is its customary appearance.

Cutting exactly through the moon, with its centre near the

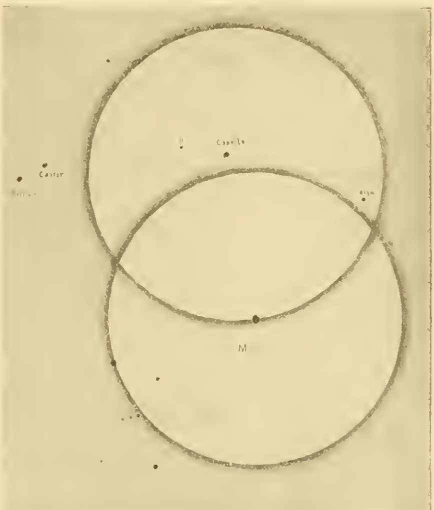


FIG. 1.—Lunar Phenomenon 1902, January 19, 9 p.m.

zenith—in the region of Capella—was another ring of apparently the same dimension and brightness, and similar to the other in every respect. It too was sharply defined on its inner edge, where it was fringed with a reddish or brownish colour. The general colour of the two rings was whitish, with a suggestion of yellow. The interior of this ring was also darker than the sky outside. There was no noticeable increase of light where the two rings intersected. They seemed to merge into one another without any evidence of the crossing.

This phenomenon was first seen at 8h. 50m. (6h. 0m. slow of Greenwich Mean Time). It was perhaps visible for some time before this. I had been observing with the large telescope when the increasing cloudiness had stopped work. It was noticed (a few minutes before seeing the phenomenon) that the seeing had suddenly got excessively bad.

The extra ring remained visible until 9h. 20m., at which time it disappeared—not all at once, but gradually and unequally.

During the time it was under observation, from 8h. 50m. to 9h. 20m., this ring revolved eastward in position angle, about

17°. The moon remained bisected by it throughout the entire visibility.

Only the brighter stars were visible, on account of the thickness of the sky, and hence its exact dimensions could not be accurately determined from the want of comparison stars. An endeavour was made to secure pointings on different portions of the ring with the 12-inch equatorial by sighting along the tube, but this was found to be impossible because of the narrowness of the slit in the dome, which prevented its being seen with sufficient distinctness.

At 9h. 17m. Algol was on the inner edge of the extra ring near its junction with the ring surrounding the moon.

At 9h. 20m. Castor was central on the ring, and at 9h. 24m. this star was on the inside edge. By this time the ring had almost entirely disappeared, only a fragment of it being visible at Castor. After this it was not seen again, though the ordinary ring remained visible for several hours. When the extra ring was disappearing, the ordinary ring became brighter, and at 10h. 30m. a bright spot (a moon dog?) became visible on its north edge.

At 8h. 50m. α Orionis was bisected by the ordinary ring, from which the diameter was found to be 48°·9.

Following are some estimations of the position of the extra ring. At 8h. 50m. a line prolonged through Pollux and Castor would touch the extra ring $8\frac{1}{2}$° from Castor. At this time Capella was by estimation (a difficult and rather uncertain determination) about one-fifth of the radius of the ring north-east of its centre. At 9h. 0m. the ring passed 7° from Castor in the line to β Aurigæ, at which time Capella was by estimation $4\frac{3}{4}$° north of the edge of the regular lunar ring.

The phenomenon was witnessed by Mr. Frank Sullivan, assistant in the large dome, and myself. I do not know that anyone else saw it.

I have never seen a similar phenomenon to this, and as it must be a rare one with reference to the moon I have thought it worth while to record the observations in NATURE. I understand that something of the kind has been seen previously with reference to the sun.

A careful drawing was made of the phenomenon, a copy of which is reproduced in Fig. 1. The exact time of the drawing is 8h. 50m. (6h. 0m. slow of Greenwich). This will explain itself. In making the drawing the two rings have been assumed to be of the same size. E. E. BARNARD.

Yerkes Observatory, Williams Bay, Wis., U.S.A., April 8. Longitude 5h. 54m. 13s.·2 W., Latitude +42° 34′ 13″.

The Education Bill.

THE Education Bill now before Parliament is of so comprehensive and important a character that it deserves to be considered from various points of view. That which is most germane to the readers of NATURE is perhaps the influence it may have upon advancing or retarding the progress of natural knowledge.

It is generally now admitted that the old notions of education, both as to subject and method, require to be improved, and that the recent advance of science, and of the applications of science to industry, claim a much larger share of attention than in days of yore. The best schools are opening their doors to this knowledge, if not welcoming it, and any change in the management of schools ought to be in this direction. How far will the present Bill fulfil this requirement? It says nothing about the curriculum of the schools, and concerns itself solely with the constitution of the local education authority, and the machinery for raising and distributing the necessary funds and for appointing representatives on the management of the schools. The personnel of the managers in the first instance may not be much changed, but their powers may be seriously limited by their superior authorities, who have the revision of the expenditure and the settlement of the rate to be levied. The influence of the electors in School Board districts will be lost; an influence which at the present time is generally directed towards rendering the schools of as much practical value as possible. The Act of 1870 secured the coming forward of men or women sufficiently interested in the subject to stand the ordeal of a popular election, and who, when elected, worked under the stimulus of public responsibility; whereas under the present Bill the managers of transferred schools will apparently retain their office indefinitely, and the nominees of the new local educational authority will always be in a minority and therefore unlikely to be able to develop the newer ideas of education.

Our methods are undergoing a slow but very real change; good object-lessons from the infant classes upward, involving the proper use of eyes and hands, are coming to the fore; with a training afterwards in such branches of natural history and physical science as may bear on the probable occupations of after life—agriculture, mining, manufactures, trade, &c.—or on domestic pursuits. Much of England's prosperity in the future will, in fact, depend upon the proper adaptation of this fundamental training to the wants of the various sections of the community. Hence the paramount importance of selecting such persons as shall not only be acquainted with the wants of the neighbourhood, but shall also be imbued with the importance of this kind of teaching.

It is interesting in this connection to observe that the statistical returns of the Board of Education show that in the schools under the management of popularly elected bodies the attention given to the scientific subjects of instruction is more than twice as great proportionally as that in the "voluntary" schools. These returns have shown a gradual advance in this respect since 1890, except that in 1899-1900 there is a small retrogression perceptible in most of the subjects, including mechanics, animal physiology, chemistry and general physics. (See British Association report on "Teaching of Science in Elementary Schools," 1901.) The cause of this is not obvious, and it is impossible to say whether it continues, as the figures for the year 1900-1 are not yet issued.

Small schools are always worked at a great disadvantage, as the children attending them cannot be properly divided into classes and have almost necessarily to be taught by one teacher. This cannot be avoided in districts of very sparse population; but the Government Bill gives direct encouragement to the multiplication of small schools, each of which will be recognised as necessary provided it can draw thirty children from some neighbouring school.

The Bill is defective in not providing that the education commenced under the code in the elementary schools should be continued in the department of higher education, whether in evening, technical or secondary schools. The only correlation attempted consists in the putting all schools within a given area under one local authority; but it does not ensure that there should be any organic connection or unity of aim between the lower and the higher schools.

I cannot help thinking that men and women elected for the express purpose, and subject to periodical re-election, are the most likely to support the more modern and practical views of education and so to enable the children under their charge to become more intelligent and valuable members of the community. J. H. GLADSTONE.

17 Pembridge Square, April 26.

Resultant Tones and the Harmonic Series.

MISS DICKINS's method of determining from the harmonic series the resultant tone would be of more worth than it is if it did not yield results which are untrue to the facts. These, as is, or ought to be, well known from the observations of the late Dr. Koenig, in some cases differ from those assumed. For example, the combination of two pure tones of the ratio 9 : 4 does *not* yield as the resultant tone 5. And in the case of the ratio 8 : 5 the resultant tone actually heard is just as likely to be 2 as 3, or both may be heard. The remark that the method is evidently as applicable to summational as to differential resultant tones is evidently made in ignorance of the circumstance that the "summational" tones are not, in fact, ever heard if the two fundamental tones are *pure*. They are one of the myths of science. SILVANUS P. THOMPSON.

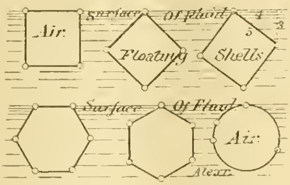
April 19.

Thin Floating Cylinders.

IN a letter to NATURE of February 18, 1897, I pointed out that a thin cylindrical floating shell was in equilibrium under the actions of its own weight and the external fluid load, the shell having its axis horizontal and just touching the surface or else completely submerged. The method was that of Rankine's conjugate load-areas, and building on this Dr. Thomson and myself made practical graphical solutions of the circular masonry arch; these were privately printed and circulated, and

met with the approval, among others, of Prof. Perry, London, and Prof. Malverd Howe, America. In revising this matter for the new edition of our "Applied Mechanics," I find that polygonal cylinders of uniform plates freely hinged at their edges and displacing their own weight of fluid and lying horizontally are also in equilibrium, provided the polygon be regular.

In the diagram the square shell is shown just reaching the surface and rolled into three positions. The proof is the same as for the ordinary statical problems on festoons of rods hinged at the ends, only now there is the external fluid pressure in addition to the weights. The fluid is kept out by face plates at the ends, the face plates having the same density as the fluid and being quite smooth, so as to allow the shell freely to change its shape. If the shell be slightly compressed it will collapse, but



the friction of the face plates and the confined air afford a slight degree of stability. The diagram shows the regular hexagonal shell, and by increasing the number of sides we arrive, as before, at the circular cylinder. In the polygonal shells there are bending moments on the sides as well as the thrust, but on the circular there is only hoop thrust, as it may be a plenum of joints. Submerging only adds a symmetrical load all round, and the shells are still balanced. As they are also balanced with the axis vertical it follows that they are in equilibrium in any position whatever.

My first letter led to some correspondence, and I hope this may be of interest to your readers. THOS. ALEXANDER.

Trinity College, Dublin, April 19.

Mycoplasm.

SINCE 1889 a fungus hyphal layer has been known to exist in the nucellar remnants of the grains of the Darnel grass, *Lolium temulentum*, and to these hyphæ have been attributed the poisonous properties of the Darnel. Later investigations have shown that the fungus could be found in the growing point of developing plants, in the inflorescence, and finally in the ovular rudiments. The manner of entrance of the fungus had, however, escaped detection. Nestler (*Ber. d. deutsch. bot. Gesellsch.*, B. xvi., 1898, p. 210) and others failed to observe the fungus in the embryo in the mature grain. The hyphæ in the growing point could not be observed before the eighth day of germination.

Eriksson has recently[1] quoted the work of Nestler and others on the fungus of *Lolium temulentum* in support of his theory on mycoplasma. According to Nestler, the embryo does not contain the hyphæ, which appear in the seedling on the eighth day. In only one case was he able to see hyphæ in the embryo. In view of the support which this work appears to give to Eriksson's mycoplasma theory, an advance note on some of my results in the investigation of the fungus of *Lolium temulentum*, which has been carried on in the laboratory of Prof. Marshall Ward at Cambridge University, may be of interest. In appropriately stained sections of the embryo taken from the mature seed of *Lolium temulentum*, hyphæ in great abundance may be seen in the growing point, sometimes but two cells from the tip; these hyphæ may be traced to their point of entrance at the juncture of the coleorhiza and scutellum on the outer surface of the latter in the region of the median longitudinal plane of the scutellum. Previous investigators had entirely overlooked the presence of a considerable amount of mycelium in that part of the grain which lies directly against the scutellum in the median basal region, where it has grown around the end of the aleurone layer. The infection takes place apparently before the grain has reached complete maturity, as the fungus is well established in the ripe grain. There can, therefore, be no question here of mycoplasm, since direct hyphal infection can very easily be demonstrated. There is no evidence to prove that the fungus is a Uredine. The detailed results, with other particulars of the nature and development of the fungus, will be published soon.

April 20. E. M. FREEMAN.

[1] Eriksson, *Ann. des Sc. Nat.*, T. xv., 1902, p. 73, says:—"Les tentatives infructeuses d'A. Nestler d'apprendre à connaître de quelle manière le champignon qu'on trouve presque toujours dans les fruits du *Lolium temulentum* est entré dans le cone végétatif de l'embryon du fruit amènent aussi la supposition d'un état mycoplasmatique latent."

Rearrangement of Euclid I. 1-32.

THE rearrangement outlined in my previous letter was devised to meet the difficulty which, as Prof. Bryan states, is the chief objection to Euclid's Elements as an elementary course. Beginners cannot solve riders because

(1) They do not grasp the reasons for Euclid's limited postulates and axioms, and never fairly understand the "rules of the game"; consequently their early attempts violate his conditions, and their rejection discourages.

(2) Too much time is occupied by the propositions, with the result that they regard them, not as tools, but as models, and imitate Euclid's methods of proof. There is nothing in 1-8 worthy of imitation.

(3) They do not distinguish between data and quæsita unless they have drawn accurate figures. It is impossible to draw accurate figures by proved methods in Euclid's scheme (*e.g.* I. 4), and we therefore have recourse to figures drawn on the principle of Artemus Ward's horses. This is the great difficulty in working riders. Allow a boy to assume the mid-point of a line and he will assume the most impossible constructions. He should never be allowed to quote a construction which he cannot perform, and no construction should be shown him without proof. Freehand copies of blackboard figures are useless; if he has drawn a dictated figure, there is no confusion between hypothesis and conclusion. There is also the additional advantage that the less intelligent feel that in drawing the figure they have accomplished something, and this frequently stimulates to further effort.

To remove these difficulties we must extend the axioms and postulates, reduce the number of standard propositions, and introduce problems as early as possible. The advocates of a purely theoretical scheme have two courses open to them—either they must teach constructions first without proof (which is extremely illogical), or they must postpone them until the completion of the theory, and therefore postpone riders indefinitely. Geometry without riders resembles arithmetic without examples.

In the scheme which we have found most successful, riders commence with the definitions. Every standard proposition is treated as a rider and evolved by the class; one proposition a fortnight is considered sufficiently rapid progress, the intervening lessons being devoted to riders.

The circle gives a method of drawing equal lines, and, with the idea of angular measurement, a method of constructing equal angles. Of course we assume the shape of the circle.

I. 15 and 32 give the fundamental fact of rotation and introduce easy theorems and numerical examples.

I. 8 with its riders elicits I. 9, and I. 4 is followed by I. 10, locus of points equidistant from two given points, I. 11, 12, 5. Having reached this point, possible riders are endless, and the only difficulty lies in their selection; many propositions of III. and IV. may be included in the riders. Every pupil can now draw an accurate figure from dictation, and knows exactly what data he has to work upon. The rate of progress may appear slow, but we are teaching Book VI. in the second year. It should be noted that I. 1 is a rider, 20 an axiom, and that 2, 3, 7, 18, 19, 21, 24, 25 are not read.

In teaching riders, theorems should, as a rule, be grouped on methods of proof; the required figure should be dictated and the class asked to prove any fact they can concerning it. A general enunciation should then be invented; in this way standard propositions for future proof are frequently suggested. It is a mistake to hurl a general enunciation at a class of beginners. Problems usually give more trouble, but if grouped on loci their difficulties vanish.

There would be no examination difficulty if papers were set on riders only. Euclid's Elements might then be reserved for university examinations—a geometrical "Paley."

Leyton Technical Institute, April 25. T. PETCH.

THE FORTHCOMING BELFAST MEETING OF THE BRITISH ASSOCIATION.

PREPARATIONS for the forthcoming meeting at Belfast are already well advanced, and careful attention is being paid by the various committees to those details which make so much towards a satisfying and successful issue.

The last meeting in Belfast was under the presidency of Prof. John Tyndall, whose famous address on that occasion will be remembered. It is interesting to note that at this year's meeting the president-elect, Prof. Dewar, F.R.S., who has so widely extended the bounds of our knowledge of the properties of liquefied gases, comes to preside over this meeting of the Association in the place where the late Dr. Andrews made his classical researches on the same subject, and where a collection of his apparatus is preserved in the laboratory where he worked.

The meeting will have ample accommodation in Queen's College and neighbouring buildings, all within a radius of three minutes' walk from the reception-room, which, as on the last occasion, will be the large examination hall of the College. Most of the sections will, as before, find place in the lecture-rooms close at hand, those sections dealing with allied subjects being close to each other, an arrangement made more easy by the recent additions to the College buildings. These include chemical laboratories, physiological and pathological departments and a students' union.

The first general meeting will be held on Wednesday evening, September 10, in the Grosvenor Hall, which seats about 2500 persons, when the president-elect will deliver his inaugural address.

The Friday evening discourse will be given by Prof. J. J. Thomson, F.R.S., on "Becquerel Rays and Radioactivity," one of the most fascinating fields of advance in modern physics and a subject which affords scope for a wide range of experimental illustration. On Monday evening a discourse will be given by Prof. W. F. R. Weldon, F.R.S., on "Inheritance." The Saturday evening lecture will be delivered by Prof. Louis C. Miall, F.R.S., and the subject will be "Gnats and Mosquitoes," about which so much interest has recently centred in connection with the propagation of malarial fever. Conversaziones will be given on the Thursday and Tuesday evenings.

It is intended to organise a loan collection illustrative of Irish antiquities and archæology and also of the progress of Belfast and its industries since remote times, and supplementing the interesting collections of a similar kind already existing in the local museums.

It has been thought best to arrange for excursions on Saturday, September 13, to the most important and interesting localities only, and to provide for large numbers in each party rather than to have many excursions, the want of interest in the less important of which might cause disappointment. Efforts will be made to facilitate the attendance of the more distinguished members on these occasions.

The chief excursions will be to: (1) Portrush and Giant's Causeway. (2) Glenariff, Garron Head and Coast Road. (3) Newcastle, Tollymore Park and Mourne Mountains. (4) Warrenpoint and Carlingford. (5) Drogheda and the Valley of the Boyne. Specially prepared pamphlets will be issued as guides to the excursions. A number of minor excursions will be so arranged as to suit the spare time that may be at the disposal of members. In connection with the meeting and the excursions, the following notes upon Belfast and the neighbourhood are of interest.

For the paragraphs dealing with geology and botany I am indebted to Mr. S. A. Stewart, for that on zoology to Mr. Robert Patterson, and for that on archæology to Mr. F. J. Bigger. Further information on these or other allied subjects will be most willingly given to members by the hon. secretaries of either the Belfast Natural History and Philosophical Society, Belfast Museum, College Square, or the Belfast Naturalists' Field Club at the same address.

Geology.—The geological characters of the counties of Antrim and Down differ very widely. The river Lagan, which separates them, is also the dividing line between the Palæozoic rocks of the south-east and the interesting secondary series to the north. The city of Belfast is built mainly on drift deposits which overlie Triassic marls and sandstones. The hills which almost encircle the city are made up of eruptive masses of dolerite covering sedimentary deposits, which consist of hard Chalk, Upper Greensand, Lias Clays, Keuper Marls and Bunter Sandstones, the interior of the county being a more or less elevated plateau. These great masses of Trap, more than 1000 feet thick, have been erupted in successive sheets, and contain beds of iron ore at certain levels. At Ballypallidy many fossil plant remains are found which determine the age of these erupted rocks as Eocene. The beautiful prismatic rocks of the Giant's Causeway are well known, and this columnar Trap is seen in several places on the coast, though in minor masses and less developed form. Good sections of the sedimentary rocks may be seen in the Belfast hills, the Antrim coast road, Portrush, and elsewhere. A much indurated but fossiliferous bed of Lias clay, so hard as to appear flinty, occurs at Portrush. In the Cushendall district some older rocks are interpolated. At Cushendun, between Cushendall and Ballycastle, is a massive conglomerate which has been supposed to be of the age of the Old Red Sandstone; where it crops out on the shore some fine caverns have been excavated by the action of the sea. Carboniferous shales and sandstones occur near Ballycastle, and coal mining in these beds is of very ancient date.

To the south and east of Belfast lies the county of Down, with its range of mountains stretching from Newcastle to near Warrenpoint. There is little variety in the rocks of the county. The higher mountain peaks are of granite, while the stratified rocks of less elevation are very much hardened Lower Silurian grits and shales. The granite masses of the Mourne Mountains are valuable building material, and they yield beryl, topaz and other much-prized minerals. Save the Silurian, there are scarcely any stratified rocks in the county. A very small patch of Permian occurs below high-water mark at Cultra, Belfast Bay, and with it a strip of Carboniferous Shale. At Newtownards is Scrabo Hill, which is an outlier of the New Red Sandstone; and at Castle Espie, on Strangford Lough, is a very small exposure of Carboniferous Limestone. Carlingford is in the county of Louth; it is a Carboniferous Limestone country, as indeed is the greater part of that county. At Coalpit Bay, near Donaghadee, are Silurian shales with graptolites.

Zoology.—The zoology of the district is exceedingly interesting, and specialists in any branch might well devote additional time to it beyond the official week. To the conchologist the district is a happy hunting-ground, fully two-thirds of the species of British land and freshwater mollusca being found here, some of extreme rarity, while several species that are very rare in England are found here in some numbers. The marine mollusca will also repay investigation, this being the only British locality for several species, while the richness of this fauna is shown by the fact that recently a single day's dredging produced one species new to science and two more new to Britain. The coleopterist will also find an interesting fauna awaiting him, several species being found here which are unknown elsewhere in Britain. September is rather late for the lepidopterist, otherwise some good things might be found. But,

indeed, remarks such as the above might be made of almost all the various branches of zoology; the district is well worth thorough searching; the Mourne Mountains have been scarcely touched by the collector, and important finds might be made at any time. The field naturalist could easily spend a profitable week on or around Lough Neagh—by far the largest lake in the British Islands—which is comparatively close to Belfast and easy of access. Here the pollan is found in great numbers, and those interested in fish can investigate this species, which is not found in either England or Scotland. The Toome Eel Fishery is also worth a visit, ten thousand pounds' worth of eels being caught annually.

Botany.—Though the peculiar group of plants, styled in the Cybele Hibernica "Cantabrian," which enrich the flora of south-west Ireland are absent in the north-east, yet the floras of Antrim and Down are both extensive and varied. The recent "Irish Topographical Botany," by Praeger, gives the plants of co. Antrim as 777, in an area of 1191 square miles; co. Down, 742 species, area 957 square miles. The coast-line of these two counties, more than 200 miles, with its sand dunes, mud flats and maritime rocks, affords suitable sites for very diverse groups of plants. The visitor to Newcastle in co. Down will find on its sandy warrens quite a number of uncommon species, while the muddy shores at Dundrum yield such plants as *Atriplex portulacoides* and *Juncus obtusiflorus*. This sea-coast is girt in almost its entire extent with hills and mountains of considerable elevation and varied mineral composition. The visitor to the Mourne Mountains will meet with siliceous rocks, granites and indurated Silurian grits and shales, yielding at Tollymore and elsewhere hawkweeds, some of much rarity. The Trappean hills which characterise almost exclusively the greater part of co. Antrim give a flora differing considerably from that of its neighbouring county. Glenariff is typical of the rugged and picturesque ravines cut deep, by the waters flowing from the moors above, into the basalt and secondary rocks of Antrim. The yew tree, formerly plentiful, still lingers on the wild cliffs of Glenariff, but apparently is near extinction. The rare umbellifer *Carum verticillatum* is plentiful on the Giant's Causeway headlands, and Scottish lovage is found on rocks washed by the sea near Portrush. The bryologist will find in "the glens of Antrim" capital hunting grounds, as their moss flora includes many species of considerable rarity. The south of the county has during last year yielded to the researches of Mr. J. H. Davies *Ditrichum vaginans*, a moss new to the British Isles. The valley of the Boyne in co. Louth, to the south, is in a limestone district, and has an extensive flora consisting of species that usually frequent calcareous tracts, but has no special features to note.

Archaeology.—The antiquities around Belfast are numerous and representative, more especially the prehistoric remains. Forts and souterrains are abundant and cromleacs numerous, the finest being the Giant's Ring quite close to the city. Here a fine cromleac is surrounded by a great earthen ring, a wonderful evidence of man's power and labour in the earliest ages. Several fine souterrains, chambered and complicated, are to be found near Antrim town. Standing stones, some holed, are also numerous, whilst Ogam monoliths occur at Connor. Celtic pre-Norman churches can be seen in several parishes with holy wells adjoining, whilst later churches with distinctive features, several round towers, such as those at Antrim, Armoy and Drumbo, can easily be visited. Of the abbeys, the most attractive are Grey Abbey, a Cistercian house, Inch Abbey, and Bun-na-Margie, a Franciscan foundation. Some ancient crosses and cross slabs, such as those at Downpatrick, Donaghmore, Dromore, Movilla and Bangor, are well worth inspection, whilst armorial stones abound in every churchyard.

The great Norman castle of Carrickfergus, with its bold central tower and surrounding ramparts, is still occupied, whilst Dunluce, the chief residence of the MacDonnells, overhangs the stupendous cliffs of the north coast, one of the finest sights in the three kingdoms. The Knights Templars had a stronghold at Dundrum, where a great circular keep and encircling battlements still defy the hand of Time.

Smaller castles abound on every hand both in Antrim and Down, showing how the Normans and subsequent settlers obtained a firm foothold, for the Irish were not given to castle-building.

In many districts primitive manners, utensils and customs are still common. Wooden vessels and quaint candlesticks, wheel cars and slipe carts, donkey creels and straw ropes, the scythe and the hand-reaper are the peasant's usual means of living and carrying on his ordinary husbandry. Nowhere can all the phases of archæology be better studied than in the north of Ireland.

Belfast—the population of which has increased from 185,000 to 350,000 since the last meeting—is well known as the industrial capital of Ireland. Its linen manufacture was in a flourishing condition in the thirteenth century, was still farther improved by the Huguenot refugees who settled in the neighbourhood in the seventeenth, and has now attained to the vastly greater scale made possible by modern machinery. Members of the Association will be given ample opportunities of visiting the most important works.

Inspection of the newer and no less important shipbuilding industry will also no doubt prove of the greatest interest, not only to engineers, but also to the travelling public who may care to see the birthplace of the White Star steamers, the first vessels in the design of which the true characteristics proper to steam-propelled vessels were fully grasped, though their great length at first evoked prophecies of disaster. Permission to inspect these yards has in recent years been only very sparingly granted, partly because of the time lost by the workmen from the distraction of their attention by visitors. Admission to these yards and engine shops will be accorded to members of the Association.

The handbook or guide to the district, a copy of which will be presented to each member, will contain specially prepared maps illustrating the topography, geology and antiquities of the district. The editors in charge of the work are Mr. F. J. Bigger, Mr. R. Ll. Praeger and Mr. J. Vinycomb.

The following subjects will be dealt with:—"History of Belfast and the District," by Mr. F. J. Bigger and Mr. J. Vinycomb; "Antiquities," by Mr. F. J. Bigger and Mr. W. J. Fennell; "Geology and Physical Geology," by Mr. J. St. J. Phillips; "Botany," by Mr. R. Ll. Praeger, Mr. S. A. Stewart and the Rev. C. H. Waddell; "Zoology," by Mr. R. Patterson, Mr. R. Welch, the Rev. W. F. Johnson and Mr. H. Lamont Orr; "Trade and Commerce," by Mr. A. G. Wilson.

Although the journey to Ireland includes the crossing of St. George's Channel, any discomfort that this may have entailed in the past has been reduced to a minimum in recent years by the excellent steamers now available. The shorter sea passages are *viâ* Holyhead and Kingstown or Greenore and *viâ* Stranraer and Larne. Members from England who prefer a night passage have a choice of three direct routes—*viâ* Fleetwood, Barrow or Liverpool. The first mentioned has the largest and best steamers; the others have one or two very good boats. Passengers from Glasgow *viâ* Ardrossan or Greenock will find the direct boats fairly good, though comparatively small, old-fashioned and often overcrowded; but the open sea passage is not long, and daylight passages are available.

The railway and steamboat companies will issue return tickets to Belfast from the principal stations in the United

Kingdom at a fare and a quarter on surrender of the usual voucher issued to members. From stations in England and Scotland such tickets will be available from September 8 to 22, in Ireland from September 8 to 28.

The local railway companies will issue return tickets at single fares to members during the meeting for short journeys, and the Belfast Street Tramways Company has kindly offered to issue passes to members for its cars free of charge. These cars pass the College gates. The accommodation for visitors has increased considerably since the last meeting in Belfast, two large and several smaller hotels having been established since then, and it is expected that a large amount of private hospitality will be offered by the citizens. J. BROWN.

THE COLLEGES OF THE UNIVERSITY OF LONDON.

IN considering the educational needs of London it is important to remember that its extended area, its large population, and its exceptional municipal government all conspire to place the metropolis in a category by itself. Local authorities and other organisations which may serve to meet the requirements of the rest of England are not suitable for the unique wants of the greatest city in the world. When framing the Education Bill now before Parliament, the Government recognised this exceptional character, and very wisely postponed for a future occasion the consideration of the coordination of existing institutions of different educational grades in London, and of the addition of necessary schools and colleges. Similarly, the University of London, as reconstituted by the Commissioners appointed under the Act of 1898, is an institution of a unique character. No other university has a similar constitution, because nowhere, at home or abroad, are the conditions of the metropolitan area duplicated.

As was pointed out in an article in NATURE in 1899 (No. 1548, vol. lx.), if, as is done in the University of London Act, 1898, the area to be served by the London University is that included within a radius of thirty miles from the University buildings, it will be found that the University has, on a very moderate estimate, to meet the higher educational needs of about seven million inhabitants. It was shown in the article referred to that to accomplish this huge undertaking with any hope of success it would be necessary to make the fullest possible use of every existing institution which could be regarded as of university standing.

It is instructive in this connection to compare the provision of university education in some other districts with that to be found in the capital. The population of Scotland is under four millions and a half, yet there are, north of the Tweed, four largely endowed and well-equipped universities, and in addition a university college. The total population of the eight large towns in England provided with university colleges is under three millions and a half; while Wales, with a population of under two millions, has three university colleges. So that, even on the grounds that London should be made as well off as the other parts of Great Britain, it may be urged, fairly and temperately, that there is need for a great and immediate advance.

For these reasons amongst others we are glad to find that University College is making an earnest appeal for largely increased funds in aid of higher education and the facilities for research in London. If the teaching University of London is to be built up on existing institutions, it is of the highest importance that University College should be incorporated with it. A short time ago a joint committee of the council of the College and the senate of the University considered the subject of incorporation, and though they have not finished their deliberations, they have agreed on certain points, viz.:—

(1) For incorporation to take place the College must be free from debt.

(2) The University will not take over University College School. Accommodation must therefore be provided on a new site.

(3) The University will require extensive rearrangements of the Medical School.

All outstanding debts are already provided for by the Drapers' Company, which has generously become responsible for them to the extent of 30,000*l.* In addition, about 60,000*l.* have been contributed, a large part of which has been given on condition that the incorporation of the College in the University is really effected. But a much larger sum is needed. To provide a site and new buildings for University College School, to refit the present school buildings and to carry out other indispensable alterations, not less than 110,000*l.* will be required. For the completion of the College buildings, thus providing adequate accommodation for both teaching and research in the many different branches of knowledge, 250,000*l.* are necessary. For departmental expenses, including the maintenance of laboratories, libraries, &c., an annual income of 6000*l.*, or a capital sum of 200,000*l.*, must be provided. For the endowment of existing unendowed chairs and for the foundation of additional professorships a yearly sum of 20,000*l.* must be forthcoming, and this represents a capital sum of 700,000*l.* In short, to perfect and complete the College and to render fruitful its incorporation in the University a sum of at least one million pounds must be found.

If our merchants and manufacturers appreciated the importance, as a factor in our national commercial success, of the higher education of the people of London, there would be no difficulty in obtaining the sum required by the council of University College. As we have chronicled from time to time, the merchant princes of America have supplied for similar institutions in the States very many times the amount asked for by University College. The Leland-Stanford University of California has received nine millions sterling from private munificence; Chicago University has been given over two and a half millions, and many other universities have similarly been provided with their necessary millions.

University College is fully justified in its appeal to the public by a splendid record of activity during the seventy-five years of its existence. The standard of the studies carried on throughout this period has been that of a university, and the yearly output of original work has not been exceeded by that of any constituent college of a British university. We cordially recommend its claims to all those who are able to be munificent, and would suggest that no more suitable way of celebrating the Coronation in London could be found than the provision of this million pounds to begin the work of establishing in the capital of the Empire a teaching university worthy of our imperial aspirations.

But, as has often been pointed out in these columns, the responsibility for the provision of educational facilities which will bring us in line with other progressive nations rests, not upon individuals, but with the State. Private benevolence is never better employed than when it is used to assist higher education and research, but it ought not to be regarded as an excuse for the neglect of a national duty; yet over and over again this is done by statesmen of both parties. Mr. Balfour occupied this position on Wednesday of last week, when speaking at the Mansion House in connection with the distribution of prizes awarded under the commercial education scheme of the London Chamber of Commerce. He acknowledged that our nation "has lagged behind all the great nations of the world, not merely in commercial education, which is a portion of technical education, but also in many of the wider and more important aspects of national education." His remarks upon the importance of studying

commerce in the spirit of impartial scientific investigation and wide knowledge were also to the point. Mr. Balfour said, in effect, that there could be no doubt about our leeway, or upon the value of broad and scientific education as the chief factor of progress, but he looked to the general community to "set itself to work to bear the great responsibilities which the needs of our country have thrown upon our shoulders."

It is only when educational provision is under consideration that our statesmen are content to leave obvious national defects to be remedied by chance munificence in the way suggested. In military and naval matters the Government is held responsible for efficiency, whatever assistance may be obtained from voluntary effort. The same principle must be applied to higher and technical education before we can hope to make our educational forces equal to those we have against us. The States which are making headway, and equipping themselves for industrial war, are those which give the greatest encouragement to the advancement of knowledge. Until our statesmen recognise this fact and act upon it, there can be no assurance against the loss of national position which must come sooner or later. The present policy of drift can only be compared with that of the man who is improvident enough to neglect to provide for old age because he hopes that some generous friend will present him with an endowment assurance.

The Government should lead the way to improving higher education, not by words, but by deeds. Practical sympathy is what is needed at present more than anything else, and the University of London offers a good opportunity for the State to show it. Let a liberal grant be made from the national exchequer, and private donors would understand that the statesmen who express fine sentiments upon the value of higher education to national welfare are actually convinced of the urgent necessities of the case. It is because this example has not been set that the various colleges of the University have to carry on their work with very inadequate resources. We commend these considerations to the Duke of Devonshire, who is to speak at the Mansion House on May 9 at a meeting to be held in support of the appeal for funds for advanced secondary education and research at University College.

It must be remembered that, when looked at broadly, this question of the provision of an adequately endowed and fully equipped University of London is a much larger one than that of securing sufficient funds to make possible the incorporation of University College in the University. Even when its incorporation has been effected, University College will be but a constituent college of what we hope is destined to be a powerful and comprehensive University, binding together all those institutions located within the metropolitan area which, by a little adaptation and some necessary expansion, can legitimately claim university rank. The consummation for which every earnest educationist in London should work is the incorporation in the University of London, in the same large way that University College desires, of all suitable colleges and polytechnics. There is King's College, which in one important respect, since it has already moved its secondary school to Wimbledon, has

FIG. 1.—Distribution of Colleges and Polytechnics in London. The order is that given in the Report of the London Technical Education Board.

1. Royal College of Science. 2. King's College. 3. University College. 4. Bedford College. 5. Central Technical College. 6. Finsbury Technical College. 7. Battersea Polytechnic. 8. Birkbeck Institution. 9. Borough Polytechnic. 10. City of London College. 11. East London Technical College (People's Palace). 12. Goldsmiths' Institute. 13. London School of Economics and Political Science. 14. Northampton Institute. 15. Northern Polytechnic. 16. Regent Street Polytechnic. 17 Sir John Cass's Aldgate Institute. 18. South-Western Polytechnic. 19. Woolwich Polytechnic.

advanced a step further on the road to incorporation than University College. The Royal College of Science, with its intimate connection with the Board of Education and its exceptional facilities for training teachers of science, would worthily fill an important part in the work of the University. The Central Technical College of the City Guilds, subsidised by the wealthy City companies, provides higher education, and could immediately take its place in the University to teach advanced technology. Bedford College, too, which has specialised in the direction of the higher education of women, must be included.

Finally, there are the polytechnics. On more than one occasion it has been pointed out in NATURE that the amount of research work accomplished in the polytechnics of greater London rivals successfully that done in many university colleges. It must, it is true, be admitted that to be worthy of the great University which it is hoped the current decade will see thoroughly established, the polytechnics will have to curtail their work. At present they attempt the education of all comers from twelve years of age and upwards. But just as it has been made a condition of the incorporation of University College that the school in connection with it shall be moved elsewhere, so in the case of the polytechnics, the existing day schools for boys and girls, where an education on the lines of the "School of Science" curriculum of the Board of Education is given, will have to be transplanted, in order that the buildings and the equipment of the polytechnics may be entirely at the disposal of the senate of the University. Similarly, the recreative side of the general training offered by many of the polytechnics will have to be provided elsewhere, for it will scarcely be compatible with the dignity of a great university to perpetuate the present arrangements for providing students with social enjoyments. With these modifications, and perhaps some others, the polytechnics, situated as they are in all parts of the metropolitan area, as will be seen from the accompanying outline map (Fig. 1), based upon the Report of the London Technical Education Board for 1900-1901, are peculiarly well adapted to become constituent colleges.

There are immediate advantages accruing from an arrangement such as that outlined of a comprehensive university, consisting of the three university colleges, the Royal College of Science, the City Guilds Institute, the thirteen or so polytechnics, and perhaps a few other more specialised institutions, all bound together as necessary parts of one university, possessing the same aspirations, and all engaged in the same work of higher education. Such an organised whole will effect far more for London than the present individual and sporadic efforts of separate uncoordinated institutions competing the one against the other. And such an university could still preserve its former character as an imperial examining board for granting degrees.

A development of this kind and on this scale will doubtless necessitate the expenditure of many times the million pounds asked for by University College. But when the inhabitants of the wealthiest city in the world are educated to understand that no spending is so profitable as that on higher education and on the endowment of research, there will be little difficulty in obtaining the necessary funds. The immediate necessity is the provision of the amount required to ensure the incorporation of University College in the University of London; but this must be followed by a strenuous endeavour on the part of all men of science and influential men in every other department of mental activity to instruct Londoners in their duty towards their city and country of providing a permanently endowed University of London, consisting of constituent colleges situated in every part of the enormous area for the higher education of which the University is responsible.

PROF. ALFRED CORNU.

CORNU was born in 1841 at Châteauneuf, and entered the great military school of Paris, the École Polytechnique, at the age of nineteen. After four years of study there he entered the École des Mines, which he quitted in 1866, thus completing a brilliant career as a student. One year later, at the age of twenty-six, he was chosen as professor of physics at the École Polytechnique, a post which he filled to the end of his life and adorned with the many results of his scientific researches.

It would be impossible in a brief review of Cornu's life to give more than the barest outline of his contributions to original knowledge. His position as a teacher gave him, amidst the material surroundings of his laboratory, the leisure to work. The beauty, the dignified ease and perfection of his investigations, the keen perspicacity of his observations, the masterly restraint, so to speak, of the scientific memoirs which from time to time he contributed to the scientific world, all bespeak a man of no ordinary capabilities, a master of his profession. Clear in his exposition of scientific matters, exquisitely clear alike in his experimental demonstrations and in the language in which he expounded their theory, he was as great in teaching as in research. Optics was his first love, and though he laboured successfully in other branches of experimental physics, it was to optics that he returned, and in the field of optics were achieved his greatest successes in physical investigation. The pages of the *Comptes rendus* and of the *Journal de Physique* bear eloquent testimony to the activity and penetration of his mind. Already, from 1863 to 1865, he had begun to contribute to the Académie des Sciences notes, the earliest of which relate to the refraction and reflection of light and to the problems of crystalline reflection. Following on the work of Jamin, he later pursued the subjects of vitreous and metallic reflection, and studied the connection between them. He showed that they were but parts of one and the same phenomenon, though affecting different regions of the spectrum, there being, as he showed, a true continuity between them.

Soon after entering upon the duties of his chair Cornu began with laborious and patient preparation those experiments upon the velocity of propagation of light which have become classical. Fizeau on the one hand, Foucault on the other, had already made determinations, each on his own lines. Foucault's value, then supposed to be the best, was $2{\cdot}98 \times 10^{10}$ in C.G.S. units. Cornu's results, of which an account will be found in some detail in NATURE of February 4, 1875, raised this figure to $3{\cdot}004 \times 10^{10}$, in vacuo, or $3{\cdot}0033$, in air. His method, which was fundamentally the same as that of Fizeau, was applied to the transit of light over a distance of 46 kilometres (or between two stations 23 kilometres apart, the one at the Observatoire, the other at Monthéry); and the instrumental perfection of his rotatory apparatus enabled him to observe up to the twenty-first extinction of the beam, thus securing a precision far in advance of that attained by Fizeau. For his determination of the velocity of light he was awarded the *prix Lacaze* in 1878, the same year in which his merits were recognised by his admission to the Académie des Sciences. In 1872 he wrote papers on the theory of electrostatics, in which he expounded the potential theories of Gauss and Green, then little known in France. They are to be found in vol. i. of the *Journal de Physique*, then recently founded by his friend d'Alméida.

For several subsequent years Cornu was occupied with researches on the spectrum. He measured the wave-lengths of the hydrogen rays with a precision previously unknown, enabling a comparison to be made between the values so obtained by experiment and the theoretical formulæ which had been

proposed by Balmer and others to express them. The suggestions of Dr. Johnstone Stoney and the later developments of Kayser and Runge will not be forgotten in this relation. He also made observations on atmospheric absorption in the spectrum, using photographic methods, at his country house at Courtenay, where he used to spend most of his vacations. He thus was able to fix the inferior limit to the ultra-violet end of the spectrum, so far as it is visible at low elevations, and found that in the laboratory air is opaque to ultra-violet waves of a lesser wave-length than $0{\cdot}185\ \mu$. His work on meteorological optics has thus been summarised by M. Guillaume :—"Such researches, in the course of which he was often led to a scrutiny of the sky, could not fail to draw his attention to the optical phenomena of the atmosphere, the study of which, though energetically pursued by the French physicists of last century, is to-day somewhat neglected. The splendid glows which were observed in the sky toward the end of 1883 furnished to Cornu an occasion to utilise the profound knowledge which he possessed of the phenomena of optics. He showed that the twilight glow, which at that time gave such marvellous charm to the sunsets, was due to a diffraction caused by fine powders, and it became evident that the formidable volcanic explosion of Krakatoa was the prime cause of it."

Cornu published an elegant method for the investigation of the optical constants of lens systems. He devised the optical lever for the measurement of the curvatures of lenses, and he perfected the Jellett prism for polarimetric work. To him is due the elegant geometrical construction in which spirals are applied to express graphically the relative intensities of the light in diffraction images. His preference for geometrical demonstrations of theorems which might otherwise be hidden under a burden of analytical symbols was well known. He worked at acoustics in conjunction with M. Mercadier, and at elasticity, and in conjunction with M. Baille redetermined the constant of gravitation. He was occupied, too, with the problems of the synchronisation of two resonant systems capable of vibration under elastic forces, these memoirs being published in 1888 and 1889, the second of them including the application of his ideas to the synchronisation of clocks for the distribution of time. His plan was closely akin to that of Wheatstone, depending on the sending, at every second, of feeble induction currents generated by the movement of a magnet attached to the pendulum of a master clock. In 1884 he reported on the electric transmission of power by M. Marcel Deprez on the Chemin de Fer du Nord. He took part in the first electrical congress at Paris in 1881. In 1886 he became a member of the Bureau des Longitudes, and in 1900 of the International Commission on Weights and Measures. He was president of the Académie des Sciences ; twice, at different periods, president of the Société de Physique ; and by general consent was elected to preside also over the International Congress of Physics in 1900.

He was elected a foreign member of the Royal Society in 1884, and was also an honorary member of the Physical Society of London. In 1878 he received for his work on the velocity of light the Rumford Medal of the Royal Society. At least twice he gave Friday evening discourses at the Royal Institution ; the last of these in 1895 on the physical phenomena of the high regions of the atmosphere.

In 1899 he delivered, with delightful eloquence and learned ease, the Rede lecture at Cambridge, on the wave-theory of light and its influence on modern physics. On this occasion, which was at the time of the jubilee celebration of Sir George Stokes, he received the honorary degree of Doctor of Science.

In Cornu, France has lost one of her most distinguished men of science, and one who, not only as investigator, but as teacher and wise counsellor, had won universal esteem and respect. A true follower of the great traditions of France in the pursuit of science, and a passionate follower of Arago, Biot, Fresnel and Fizeau, he was in his own person much more than this. He was the ideal of a well-equipped, well-balanced, intellectual leader in scientific thought.

SILVANUS P. THOMPSON.

M. VIGNON'S RESEARCHES AND THE "HOLY SHROUD."

AT the meeting of the Paris Academy of Sciences on April 21, some remarkable photographs of brownish stains found on the "Holy Shroud" kept in the Treasure Chamber of Turin Cathedral, and traditionally said to be the winding-sheet of Christ, were exhibited in connection with a paper by Dr. P. Vignon, of which a translation from the current number of the *Comptes rendus* of the Academy is given below. Upon reproducing these stains by photography, Dr. Vignon found that he obtained a realistic picture of a human figure, and the suggestion is that the picture is actually a representation of the body of Christ, produced by radiographic action from the body, which, according to ancient texts, was wrapped in a shroud impregnated with a mixture of oil and aloes. We give Dr. Vignon's paper, which it will be noticed is confined to an account of principles relating to radioactivity.

ON THE FORMATION OF NEGATIVE IMAGES BY THE ACTION OF CERTAIN VAPOURS.

IT is known, from the work of M. Colson, published in the *Comptes rendus* of the Academy of Sciences in 1896, that freshly cleaned zinc emits vapours at the ordinary temperature which are capable of affecting photographic plates in the dark. The researches of Russell have also shown that the striations of a plate of zinc reproduce themselves on a photographic plate. But it is a long step from this to the realisation of an object in relief. I have succeeded in obtaining images either with medals powdered with zinc, or with bas-reliefs or objects fully embossed, in plaster, and rubbed with zinc powder. These images are negatives, not by the inversion of light and shade, since they are formed in the dark, but by the fact that the reliefs give more energetic impressions than the cavities. To interpret these it is necessary then to invert photographically ; positive images are then obtained in which the scale of relief is scrupulously respected, which is far from being the case in normal photographs of the same objects illuminated from the front. Naturally, upon images made at a distance, the reproduction of the most minute details could not be expected, the precision of the detail obtained being less as the distance increased. The clearness of the image depends upon the rapidity with which the action diminishes when the space increases between the emissive surface and the receiving screen.

From a point of the active surface let a perpendicular be lowered on to the receiving plate ; the foot of this perpendicular constitutes the centre of a circle which makes a more energetic impression in its central region than on its edges ; the clearness of the image will thus be greater the smaller the surface of the circle acted upon, and this surface varies inversely as the rapidity with which the actions decrease when the distance increases. It is on this account that the images correspond very nearly to those which would be realised if the actions were produced only according to the orthogonal projections of the different points of the active surface.

It is a curious point that the images converted into positives frequently give rise to the impression of having been lit from above.

This will be the case when a plane, such as the forehead, is seen from the front and forms at the same time a strong relief, whilst a plane near it is rapidly shifting, such as, for example, the region which connects the superciliary arch to the eyeball. When this plane shifts it appears to sink into a deep shadow.

The truly specific character of these negative images which arise from action at a distance lies in the softness of the contours. The limit of the visible portion is the result for the eye of the receding of the surface. If this falling back takes place at a small distance from the receiving plane, the contour is still marked, though vaguely ; but if this falling away is produced

only at a distance greater than that at which the vapours can act, no corresponding effect is produced in the image, which gradually weakens up to its borders by insensible gradations until it disappears altogether.

Practically in spite of the softness of the details and the outlines, the impressions produced by vapour are far from consisting of simple shadows; if the object is in strong relief, the image is energetic and well marked; it appears simply as if the object were seen through transparent gauze, or as if it had half emerged from a fog.

Negative images have also been obtained by acting with ammoniacal vapours upon cloths impregnated with a mixture of powdered aloes and olive oil; it is known that aloes contains a principle which turns brown and is oxidised under the influence of alkalies in moist air. A plaster hand covered with a suède glove which has been moistened with a solution of ammonium carbonate acts similarly. There is obtained in this way a sort of print of the hand, a negative softened at the edges and wanting in proportion in so far that the points where the hand is too far from the cloth are too faint, the points of contact of the hand and cloth, on the other hand, being too strongly marked. The fermentation of urea, easily brought about by the addition of a little urine, leads to the formation of ammonium carbonate and thus causes the browning of the aloes. The fermentation of a febrile sweat, rich in urea, leads to the same result, as is already well known.

The extension of Dr. Russell's researches on the photographic activity of certain bodies in the dark, contained in the above paper communicated to the Paris Academy by M. Vignon, has given rise to a most curious discussion.

There is a so-called "Holy Shroud" at Turin in which tradition states the body of Christ was wrapped after the Crucifixion. An article in the *Times* thus refers to it and its connection with M. Vignon's work:—

"It is said to have been brought from the East in the fourteenth century, and in the following century it passed into the hands of the House of Savoy, and was deposited at Chambéry. Finally, it was transferred in 1578 to its present resting-place by Duke Emmanuel Philibert, who wished to spare Carlo Borromeo, the sainted Archbishop of Milan, the fatigue of a pilgrimage to its distant Savoyard shrine. The Shroud bears upon it, traced in hues of brown, what is alleged to be a double impression of the figure of Our Lord, the outlines both of the face and back of which have reproduced themselves with wonderfully distinct exactness. So seldom, however, is it exposed to view that this remarkable characteristic had almost been forgotten when, in May, 1898, some photographs specially taken of it by Signor Secondo Pia, of Turin, with the consent of its possessor, the King of Italy, once more drew attention to this strangely living likeness. Eighteen months ago these photographs came under the notice of M. Vignon, who, recognising their exceptional importance, at once began that inquiry of which the results were made public in a paper communicated to the Académie des Sciences."

In Paris, therefore, it has been generally accepted that a demonstration has been given by science of the authenticity, not only of the so-called shroud, but of all the historical events connected with it, and a much closer rapprochement between science and theology is predicted for the future.

Here, however, difficulties have been raised. Father Thurston, a learned Jesuit, writes to the *Times* as follows:—

"Before we can profitably discuss the value of Dr. Vignon's scientific explanation of the marks on the 'Holy Shroud' a serious difficulty of quite another order has to be cleared up. The Abbé Ulysse Chevalier claims to have proved to demonstration that the linen winding-sheet exhibited at Turin is a spurious relic manufactured in the fourteenth century, and, as the writer believes, with fraudulent intent. M. l'Abbé Chevalier is a scholar of distinction, and of his perfect loyalty to the Catholic Church there can be no possible question. Moreover, his essay ("Étude Critique sur l'Origine du S. Suaire," Paris, Picard, 1900) has been warmly welcomed by the more critical journals devoted to hagiography. In the Bollandist periodical, the *Analecta Bollandiana*, for instance, its Jesuit editors state (vol. xix., 1900, p. 350) that the Abbé Chevalier's discussion of the subject is final, and that 'il ne reste plus qu'à proclamer "à haute et intelligible voix," comme le voulait le Pape Clément VII.: "Hæc figura . . . non est verum sudarium Domini Nostri Jesu Christi."'

"They go on to state that the story of the 'image of the shroud' given by Geoffroy de Lirey to the college founded by him in 1353 is not lost in the mist of ages, and does not happen to present any of those obscurities by which the historian who wishes to impart his own laboriously-acquired conviction to others must at times find himself baffled. We have, for instance, the document addressed to the Pope by Bishop Peter d'Arcis, in which he denounces the fraudulent dealing of the Chapter of Lirey, who for motives of avarice pretended that miracles were worked by this shroud, whereas his predecessor in the see of Troyes had officially investigated the matter and proved it to be a forgery. 'Et probatum fuit eciam per artificem qui illum (pannum) depinxerat, ipsum humano opere factum, non miraculose confectum vel concessum.'"

There is also another difficulty. It is stated that there is at least one other Holy Shroud in another holy place.

NOTES.

THE governing body of the Jenner Institute of Preventive Medicine has appointed Major Ronald Ross, F.R.S., whose name is well known in connection with his researches on malaria, to be head of a new department in the Institute at Chelsea.

WE learn from the *British Medical Journal* that the Legislature of New Jersey has passed a Bill which sets aside 10,000 dollars for the support of an experiment station where scientific investigations are to be made into the habits and breeding-places of mosquitoes and their relations to public health.

WE regret to see the announcement of the death, at the age of sixty, of M. Henri Filhol, professor of palæontology at the Jardin des Plantes, Paris; and also of Prof. I. L. Fuchs, professor of mathematics in the University of Berlin.

THE council of the Royal Institute of Public Health has conferred the Harben Gold Medal for the year 1902 upon Prof. W. R. Smith, late medical officer of the School Board for London, in recognition of his eminent services to the public health.

THE Washington correspondent of the *Times* reports that Lord Kelvin and Mr. Westinghouse both gave evidence on April 24 before a committee of the House of Representatives appointed to consider the present system of coinage and weights and measures. Lord Kelvin advocated the passing of a Bill to substitute the metric system for the standard now employed in the United States. Mr. Long, Secretary of the Navy, expressed the hope that England would take the lead in this change, but said that if England did not the United States should, and England would then follow. Mr. Westinghouse supported the Bill, but declared that it would take ten years for the people to learn to use the metric system.

IN connection with the second International Congress of Medical Electricity and Radiography, to be held at Bern on September 1-6, there will be an exhibition of apparatus relating to electro-physiology, electro-therapy and radiography. The physiological apparatus will be exhibited in the Physiological Institute, and will be in charge of Prof. Kronecker, director of the Institute, to whom communications relating to it should be addressed. The induction coils, contact-breakers, vacuum tubes and other apparatus connected with the production and uses of Rontgen rays in medicine will be in charge of Herr O. Pasche, chief of the Röntgen Institute of the Bern

Hospital. The exhibition will be opened on August 29, and intending exhibitors should communicate as soon as possible with Herr Pasche, Röntgen Institute am Inselspital, Bern.

At the present time, when much attention is being given to the reform of mathematical teaching associated with the name of Prof. Perry, the pamphlet entitled "The Cultivation of the Mathematical Imagination," by Miss Mary Everest Boole (Colchester: Benham and Co., price 6*d.*), appears very opportunely. The methods advocated by the authoress belong chiefly to the kindergarten stage of education, but there are many suggestions that are appropriate to a slightly more advanced stage; the central idea is always that of leading up to general truths by means of concrete processes. The pamphlet should be very helpful to teachers who wish to find out how to prepare the minds of young children to receive formal mathematical instruction.

Prof. R. W. Wood writes:—"It may perhaps be a matter of some interest to teachers whose laboratory facilities are limited to know that solid carbon dioxide can be obtained from the sparklets now sold everywhere for a penny or two for the aëration of beverages. The larger of the two sizes gives the best yield, of course. It is best to cool the sparklet in ice and salt for a few minutes before the experiment, and doubtless the amount of solid obtained would be still further increased by chilling the metal reservoir with which the bottles are fitted. A small square of black velvet should be held, or tied with a turn or two of string, over the end of the tube which delivers the gas into the fluid. The nap of the cloth should be on the inside, and the part over the tube should form a little bag about the size of a marble. On discharging the sparklet and quickly removing the bag, the interior will be found to be lined with the snow-white solid, with which a small drop of mercury can be easily frozen. The substance shows off most beautifully on the jet black surface of the velvet."

The death is announced of Mr. William Henry Penning. After pursuing a course of engineering under Mr. C. H. Gregory, he joined the staff of the Geological Survey in 1867 and was engaged in mapping portions of Essex, Suffolk, Cambridgshire and Lincolnshire. He was joint author of memoirs on the geology of the neighbourhood of Cambridge, Lincoln, and parts of Essex. He was author also of "A Text-Book of Field Geology," 1876 (edit. 2, 1879), and of "Engineering Geology," 1880. In 1882, through ill-health, he resigned his post on the Geological Survey and spent some time in South Africa. He died on April 20. We have also to regret the death of Mr. Joseph Nolan, who joined the Geological Survey in Ireland under Jukes in 1867, and after many years of active service in the field became in 1890 resident geologist in the Dublin office. He was author or part author of several memoirs in explanation of the Geological Survey maps. He retired from the public service in 1901 and died on April 19.

A strong earthquake was felt round Lake Baikal on April 12. It began at Irkutsk by a severe shock at 6h. 40m. a.m., the pendulum of the observatory being deflected by 22 mm. About twenty fairly severe shocks followed during the first minute. Groups of shocks next occurred, the strongest of them being at 7h. 13m., 7h. 31m., 7h. 36m. and 8h. 14m. All these shocks could be felt even without instruments, their force attaining the value of 5 in the seismic scale. The earthquake was widely felt round Lake Baikal. At Selenghinsk the chief disturbance travelled in a direction from S.W. to N.E. and the following shocks were noticed:—at 7h. 0m., 7h. 50m., 7h. 54m. and 8h. 35m. At the village Snyezhnaya, on the eastern coast of the lake, several chimneys were destroyed and crockery was thrown down. Further east, at Verkhneudinsk, and on the western coast, the shock was much feebler. During the night of April 10–11 a very strong earthquake was felt in the north of Finland. At Uleaborg window panes rattled and crockery fell from its place. Shocks of earthquake continue also to be felt at Shemakha. Two severe shocks were noticed on April 17 at 10h. 0m. and 10h. 30m. p.m.

It seems at first sight to be a bold statement to put forward that the study of the distribution of plants may be dated back to the time of Alexander the Great. But no more weighty opinion could be obtained than that of a scholar who has combined the study of classics and botany. Herr Hugo Bretzl, as a thesis for his doctorate in Strassburg, has made a careful study of Theophrast's "Plant-geography," and comes to the conclusion that from the description there given of the air-roots of *Ficus bengalensis* the writer must have been able to refer to the original accounts of Alexander's expedition. The brochure received gives two chapters from the whole work, which is to be published in book form and promises to be exceedingly interesting. Not only does the author show that the Greeks realised such facts as the absence of the pine in all the countries which intervene between Macedonia and India, but incidentally his references suggest that the Aristotelian writers have not received due justice at the hands of other writers of historical botany.

It will be remembered that in a recent issue notes of the discovery of a blood parasite occurring in man and belonging to the genus Trypanosoma were recorded. The case was one of a European, whose chief symptoms were irregular rises of temperture with afebrile intervals, the attack being accompanied by increased frequency of respiration and pulse. The parasite was present only during the febrile attacks, and whilst it closely resembled *T. Brucei* in form and staining reactions, it was, however, considerably smaller and in fixed specimens assumed a characteristic "set." Another striking feature, which reminds one of the diseases known as Nagana and Surra in horses and cattle, is the occurrence of œdema of the eyelids and feet. Nepveu claims to have discovered this parasite in man in Algiers, but his description is very imperfect and raises considerable doubts as to whether what he saw were really trypanosomes. Mr. J. Everett Dutton, who described the parasite occurring in the blood of a European at Bathurst, West Africa, has within the last few days added the most interesting observation that the parasite occurs also in native children. Whilst examining for malaria parasites a large number of microscopical blood preparations of the native children of a small village, a few miles nearer the mouth of the River Gambia than Bathurst, he found in one preparation a number of trypanosomes resembling in every way those found in the case of the European before recorded. This second observation opens up a large field for further investigation and points to the extreme importance of the study of the diseases of natives, especially from a parasitological point of view, in West Africa and other parts of the world.

The Meteorological Office Pilot Chart for May gives a short account of submarine earthquakes and the curious sensations they produce on board ship. Within the basin of the North Atlantic the fairly well-defined seismic regions are near the equator, between 19° and 33° W.; about the West Indies; from the Cape Verde Islands north-westward to about 33° N., 41° W.; and from 34° to 45° N., 13° to 30° W. The ice season this spring is very late, no bergs having been reported down to April 16. The St. Lawrence River was open for navigation at Quebec on April 3, an unusually early date. Numerous observations show that during the month of February last the temperature of the surface water of the Atlantic was below the average over a space extending south-westward from the British

Isles as far as 30° W. longitude. On shore the month was the coldest we had experienced for seven years, the air temperature being from 3° to 5° under the normal for various localities.

THE Meteorological Council has issued a valuable paper entitled "Temperature Tables of the British Islands." The work is divided into two parts: (1) The results derived from thirty years' hourly observations (1871–1900) for the four observatories Valencia, Aberdeen, Falmouth and Kew, showing the means and extremes of temperature for each day of the year and for the month; (2) the means and extremes for each month and for the year for 117 stations, with records of not less than fifteen years. In order to give an adequate representation of monthly temperatures of the London area, a table for Greenwich is included, with the consent of the Astronomer Royal, which gives data for sixty years. In the diagrams representing the seasonal variations at the observatories, the curves for maximum and minimum readings are printed on tracing paper, so that they can be superposed one upon the other, or upon the curve showing the mean values. A special feature, it is stated, in the treatment of the seasonal curves is an attempt to define a normal seasonal variation of temperature by the harmonic analysis of five-day means, to which daily averages and individual observations can be referred.

THE first number of the third volume of the *West Indian Bulletin* is devoted to a summary of the business transacted during the Agricultural Conference at Barbados in January last; to full reports of a number of papers on various phases of the sugar industry, with short accounts of the discussions on them; and to two communications of a general character—"The Organisation and Functions of Boards of Agriculture" and a "Report of the Chemical Section at the Conference." With the approval of the Secretary of State it is proposed by the Commissioner shortly to commence the publication of a new fortnightly review, to be called the *Agricultural News*, intended to contain in popular form agricultural information suited to the circumstances of the West Indies.

A PAPER by Mr Horace C. Richards, on the harmonic curves known as Lissajou's figures, is not the least interesting feature of the *Journal* of the Franklin Institute for April. The diagrams traced by the aid of a harmonograph are remarkably perfect and beautiful.

AN illustrated account of M. Santos Dumont's Parisian experiments is now given in *Prometheus*, No. 642. It includes reproductions of photographs showing the results of the accidents on August 8 and September 6, 1901; the successful ascents of October last are illustrated by views of the balloon when starting and when rounding the Eiffel Tower and a chart of the course.

THE *Rendiconti* of the Lombardy Academy notes that the Bologna Medical and Surgical Society offers a prize of 500 lire for an essay on sero-diagnosis in tuberculosis. Further, the "Olympic Academy" of Vicenza offers a prize of 3160 lire for a study of the Italians living on the South American continent, including more particularly the question of emigration and the relation between the colonists and their mother country.

THE Deutsche Mathematiker-Vereinigung has decided on a new departure in regard to the publication of its *Jahresbericht*. Under the editorship of Prof. A. Gutzmer, of Jena, this publication will in future appear monthly instead of annually, and among other features it is proposed to include academic dissertations, inaugural addresses, obituary notices both of members and of non-members, discussions on questions of teaching, notices of such undertakings as catalogues of current literature or the publication of Gauss's works, accounts of the meetings of societies, and notes and queries.

WE have received the April number of *Le mois scientifique*, which is devoted to a summary of recent books and publications on horticulture and botany. Among these we notice two new books on the cultivated plants of the south of France, one by M. Sauvaigo dealing with the Mediterranean coast, the other on southern flowers generally by M. Granger, and a new flora of France by M. A. Acloque.

UNDER the title of *Théorie nouvelle de la Loupe*, M. G. Quesneville has published, in Paris, a small *brochure* dealing with the optical properties of lenses, considered with especial reference to vision. The principal difference between the present and the conventional treatment is that here account is taken of what happens to the rays of light, not only during their passage through the system of lenses considered, but also after they enter the eye.

THE manufacture of butter with sterilised cream with the view of preventing the spread of tuberculosis is discussed by Drs. Serafino Belfanti and Costantino Coggi in the Lombardy *Rendiconti*, xxxv. 7. In Sweden and Denmark pasteurisation is already adopted on a large scale, but in Germany and Italy a prejudice still exists against butter made with cream that has been subjected to this precautionary measure. The paper shows that the process, so far from being detrimental to the quality of butter, may actually prove of commercial value, and that the problem of preventing the diffusion of tuberculosis by means of milk does not involve such great pecuniary sacrifices as have been sometimes anticipated.

THE Geneva Society of Physics and Natural History has just issued the first part of volume xxxiv. of its *Mémoires*, containing reports of the work done during 1900 both in physical and biological science. Among the most interesting results we notice M. A. Brun's observation during the summer of 1900 of a peculiar kind of snow on Mont Malet, called "neige de Caucase," or Caucasian snow. It is a porous snow the grains of which attain a size of as much as three millimetres, and their want of adherence may readily give rise to avalanches. A new station at the Hospice of the Great St. Bernard is another feature noted in the *Mémoires*. The observations are made at the usual hours of the Swiss meteorological service, and the building is situated to the north-east of the old hospice. This departure is largely due to the energy of Prof. R. Gautier, who has equipped the station with thermometers and hygrometers specially adapted to high mountain work, and whose efforts have been ably supported by the monks.

WE have received a copy of an address on the teaching of biology delivered by Prof. Haberlandt on the occasion of the opening of the new scientific and medical institute at the University of Gratz on December 9, 1899.

FROM the Report of the Director for the year 1899–1900, it appears that so long ago as 1857 a Museum was established in the town of Trivandrum, Travancore, but that for many years its condition was far from flourishing. By the addition of a public garden and menagerie, affairs have been placed on a better footing; and it is satisfactory to learn that the museum is now devoted to the illustration of local zoology. The following sentence from the director's Report is somewhat remarkable:—"In 1890 I succeeded Colonel Ketchen as Honorary Secretary and received the honorarium usually given to the Honorary Secretaries."

IN vol. xxiv. (pp. 499 566) of the *Proceedings* of the U.S. Museum, Mr. W. H. Dall describes and figures a number of new or hitherto imperfectly known shells, mainly American, in the collection of which he has charge. A large number of these, belonging to Buccinum, Trophon and allied forms, are

from Alaska and other parts of the Pacific coast of north-western America. Conspicuous among them is the handsome shell from Unalaska Island on which the genus and species *Beringius crebricostatus* were established by the author. A very large number of species belong to that group of Trophon which the author distinguishes as Boreotrophon.

THE numerous cruises of the U.S. Fish Commission steamer *Albatross* undertaken for the purposes of dredging, sounding and other objects connected with biology and hydrography are so important, and the literature relating to them is distributed through such a large number of serial and other publications, that all naturalists will be pleased to learn that a concise bibliography relative to the work of the vessel has been published. The task of compiling this record, which appears in

The U.S. steamer *Albatross* dredging, showing port boom rigged for surface towing.

the Report of the U.S. Fish Commission for 1900, has been entrusted to Mr. C. H. Townsend, the chief of the Fishery Division of the Commission, whose familiarity with the work of the ship, on board of which he served as naturalist from 1886 to 1900, rendered him peculiarly fitted for the task. The record comprises 172 closely printed pages, and is accompanied by a chart and illustrated with several views of the vessel, one of which is here reproduced. The first cruise took place in 1883, and the prime object of the work was the investigation of the fisheries and fishing-grounds. From 1892 to 1898 comparatively little work of this nature was, however, accomplished, owing to the vessel being employed on other services. For instance, at one time it was employed in Alaskan waters in connection with the Committee on Indian Affairs, on another occasion in laying the cable between California and Hawaii, and on a third occasion it was told off for service during the war with Spain. In spite of these withdrawals from its proper sphere, the vessel has made 1786 dredging and trawling hawls, at all depths down to 4173 fathoms, and extending over a very large area; while the soundings taken number at least 4000.

MESSRS. WHITTAKER AND CO. announce that they will shortly publish in their specialist series a work entitled "Mechanical Refrigeration." The volume is by Mr. Hal Williams, and will deal with the whole field of ice-making and cold storage.

THE edition of the "Life of Charles Darwin," just published by Mr. John Murray at the modest price of half-a-crown, is a marvel of cheapness. The volume contains 348 pages, clearly printed on good paper and neatly bound; so that naturalists who do not possess a copy of the life of their master should hasten to add it to their libraries. A life like Darwin's inspires everyone with reverence for his greatness and the desire to walk humbly in the same light. The record and reminiscences of such a great career cannot be too widely read.

TO suggest subjects to study in outdoor nature, and facilitate the record of the observations, Miss W. L. Boys-Smith has prepared a "Nature Note-Book," which has been published by Messrs. Allman and Son. A few hints are given concerning obvious characteristics, dates of appearance and habits of some common animals and plants, and thirty-three questions set by the National Froebel Union to test observation are printed at the end of the book. The remaining pages are ruled for records of observation and remarks, and for drawings. In connection with the revival of nature study or natural history, the note-book should be of service to young students.

MR. JOHN MURRAY will publish almost immediately an important volume by Major Molesworth Sykes, entitled, "Ten Thousand Miles in Persia." During the eight years which Major Sykes spent in Persia, he travelled over and explored the country from the Caspian Sea to the Persian Gulf, and from the Tigris to the frontiers of Afghanistán and Baluchistán, his journeys extending to quite ten thousand miles. The book about to appear will contain a record of his travels, with special reference to the geography and history of the country as well as to its commercial resources, the opening up of trade routes and the journeys of Alexander the Great and Marco Polo.

NEW editions of two volumes in the comprehensive series of manuals of science and technology published by the house of Ulrico Hoepli, Milan, have recently been received. One is the third edition, revised and enlarged, of "Magnetismo e Elettricità," by Prof. F. Grassi. The book contains a good account of the principles of electricity and magnetism, and gives much more attention to the applications of these sciences than is usually the case in similar manuals. Another third edition is the "Manuale del Chimico e dell'Industriale," by Prof. L. Gabba. This volume consists of a valuable collection of tables of standards, physical and chemical data, analytical processes, and similar information of service in laboratories and assay offices.

THE additions to the Zoological Society's Gardens during the past week include a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Lady Stanley; a Scops Owl (*Scops giu*) European, presented by Miss G. Ashley Dodd; a Robben Island Snake (*Pseudaspis cana phocarum*) from South Africa, presented by Mr. T. E. Cartwright; an Antillean Boa (*Boa diviniloqua*) from the West Indies, presented by Mr. E. S. Graham; a Derbian Wallaby (*Macropus derbianus*), three Long-necked Chelodines (*Chelodina longicollis*), two Limbless Lizards (*Pygopus lepidopus*) from

Australia, twenty-one Giant Toads (*Bufo marinus*) from South America, three Spiny-tailed Iguanas (*Ctenosaura acanthura*) from Central America, a Dark Salamander (*Amblystoma tenebrosum*) from California, two Long-tailed Weaver-birds (*Chera progne*) from South Africa, a Starred Tortoise (*Testudo elegans*), three Bungoma River Turtle (*Emyda granosa*), a Ring-necked Parrakeet (*Palaeornis torquatus*) from India, deposited; two Nylghaies (*Boselaphus tragocamelus*, ♂ ♀), four Yellow-billed Liothrix (*Liothrix luteus*) from India, a Grison (*Galictis vittata*), a Condor Vulture (*Sarcorhamphus gryphus*, ♂), four Grey Teal (*Querquedula versicolor*, ♂ ♂ ♀ ♀) from South America, two Mantchurian Crossoptilons (*Crossoptilon mantchuricum*, ♂ ♀), a Bar-tailed Pheasant (*Phasianus reevesi*) from China, a Common Crowned Pigeon (*Goura coronata*) from New Guinea, two White-fronted Geese (*Anser albifrons*), four Bearded Tits (*Panurus biarmicus*), a Waxwing (*Ampelis garrulus*) European, purchased; five Indian Wild Swine (*Sus cristatus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SIGNALS FROM MARS.—In the *Proceedings* of the American Philosophical Society for December 1901 (vol. xl. No. 167), Mr. Percival Lowell refers at some length to the observations that led to the announcement in the Press that Mars had been signalling to the earth on a night in December 1900. It may be mentioned that the *original* despatch read as follows:—"Projection observed last night over Icarium Mare, lasting seventy minutes." (Signed) "Douglas." In the present paper Mr. Lowell describes in detail some of the individual observations, and points out how the Flagstaff observations of 1894 showed that on general principles the Martian projections were most probably not due to the existence of mountain peaks. A close study of the surface markings led both Messrs. Lowell and Douglas to the result that these several projections were not caused by such permanent surface markings as mountains, but were the effect of clouds floating in the planet's atmosphere. At the opposition of 1894 more than 400 projections were seen in the course of nine months, and since that time other observations have helped to show that the non-reappearances of these projections at such favourable times when, if they were mountains, they should have been seen, have proved their non-permanent character. In fact, permanences like mountains were found to do violence to the observations, and the alternative explanation chosen was something floating in the planet's atmosphere and capable of reflecting light, or, in other words, clouds. Mr. Lowell, in his concluding remarks, says that the surface marking, Icarium Mare, is undoubtedly a great tract of vegetation, and the observation of December is completely explained if it be assumed that a cloud was formed over this region and rose to a height of thirteen miles, and then, travelling east by north at about twenty-seven miles an hour, passed over the desert of Aeria and there was dissipated after an existence of three or four days. The Flagstaff observations thus tell us that mountains on Mars, if there be any, have still to be discovered.

THE ORION NEBULA AND MOVEMENT IN THE LINE OF SIGHT.—Prof. H. C. Vogel communicates to the *Sitzungsberichte der Kön. Preuss. Akad. der Wissenschaften zu Berlin*, March 13, an account of the results which he and Dr. Eberhard have obtained with reference to the measurements of the spectrum of the Orion nebula taken for the determination of motion in the line of sight. The instruments used were the photographic refractor of 32·5 cm. aperture and 3·4 metres focal length, and a spectroscope with three prisms, the latter being supplied with electrical heating for maintaining a constant temperature during the time of exposure; the comparison spectrum was that of iron in every case. The measurements of all the photographs were made by Prof. Vogel and Dr. Eberhard independently of each other, and the region of the nebula investigated was practically the same as that examined by Prof. Keeler in 1890 and 1891, so that a direct comparison with his results can be made. The following table shows the values of the velocities in kilometres per second relative to the sun obtained from measurements at different parts of the Hγ line.

	Vogel. Km.	Eberhard. Km.
Position angle 90° from star θ' Orionis Δ=0'·8; beginning of Hγ line ...	+16	+17
At θ' ...	+16	+16
Position angle 270°; Δ=0'·6 most intense portion of Hγ line ...	+12	+11
Position angle 270°; Δ=1'·2 to 1'·4 near end of Hγ line ...	+8	+12

The mean velocity relative to the sun obtained by Keeler, who used the Hβ line, was + 17·7 ± 1·28 kilometres, a value not very much removed from the above-mentioned determination.

Another interesting point obtained from a close examination of the Hγ line was the distinct irregularity or hump of this line in the nebula spectrum, and both Prof. Vogel's and Dr. Eberhard's measures give velocities relative to the sun of + 6, + 28, + 11 and + 6, + 41, + 28 respectively to three chosen points on this line. It is pointed out that the measurements were difficult, and on account of the faintness of the line probably not very accurate. Keeler, however, looked for relative motion in the nebula itself, and came to the result that from his observations there were shifts which indicated relative motion in the nebula amounting to 21 kilometres per second, and in the brightest part of the nebula shifts corresponding to a third of this amount were detected. It may be mentioned also that Sir Norman Lockyer, in his communication to the Royal Society (*Phil. Trans.*, 1895) on the spectrum of the Orion nebula, obtained evidence of internal motion in the nebula in the distortion of the lines 4471 and 4495. These lines were found to be sharply bent, whilst the others remained straight. Unfortunately, only one photograph was secured, and it was suggested that in the absence of others it was possible that this displacement might have been due to a distortion of the photographic film. There seems little doubt, therefore, that these deformations and anomalies of the Hγ lines observed at Potsdam are real indications of relative motion in the nebula itself, and the values for the velocities given will perhaps be more accurately determined when further photographs have been secured and measured.

THE RELATIONS BETWEEN METALLURGY AND ENGINEERING.[1]

THE lecturer stated that this was the subject with which the council had requested him to deal in his lecture, but it must not for a moment be imagined that the metallurgic art was not included in the wide range covered by the Institution, which had, from its earliest days, given prominence to the work of metallurgists. He quoted Mr. G. P. Bidder, who, in his presidential address to the Institution delivered in 1860, said "that if he were called upon to define the object and scope of the profession of civil engineer, he would say that it was 'to take up the results discovered by the abstract men of science and to apply them practically for the commercial advantage of the world at large, and to diffuse their beneficent influence among all classes of his fellow citizens.'" He hoped to be able to show that metallurgists practising an industrial art had helped the engineer to do this, and in evidence that such was the case, he quoted from the presidential address of Sir John Fowler, words to the effect that engineers had been more assisted by members of the Institution and by distinguished men of science generally in relation to iron and steel than as regarded any other material. It was in connection with iron and steel that the illustrations of the lecture would be mainly given. It might at first be thought that the relations between metallurgists and engineers, which had become so close and enduring, arose quite simply from common interest. The case was, however, far from being so simple; communication between those who extracted metals from their ores and adapted them for the use of the engineers, who actually employed metals in construction, was seldom, at the outset, quite direct. The relations with which the lecture dealt had been strangely stimulated by the intervention of men who, in many cases, were neither engineers nor metallurgists, but were men whose lives had been devoted to

[1] Abstract of the tenth "James Forrest" Lecture, delivered by Sir W. C. Roberts-Austen, K.C.B., F.R.S., at the Institution of Civil Engineers on April 22.

abstract science. Such men recognised the value of certain metals and alloys for definite uses, they investigated their mechanical properties, and proclaimed their merits to engineers. The intervener then disappeared, leaving behind some coefficient or constant bearing his name by which he was gratefully remembered. As an instance, Galileo's estimation of the tensile strength of copper cylinders, and Young's determination of the rigidity of steel (which had resulted in Young's modulus) were cited.

It was not easy to fix the period in industrial history at which the metallurgist began to give the engineer material assistance. If in this country Stonehenge were taken as a starting point, the architect-engineer who designed that crowning example of Neolithic art could not have received any assistance from the metallurgist. That stately structure arose from the plain at a time when bronze tools were known but were not in general use, and this period had recently been fixed by Mr. Gowland at about 2000 B.C. In another phase of engineering work it was known that Rome, in the days of her occupation of this country, trusted to the metallurgists of our island to supply the lead which was so extensively used in the Eternal City. The fourth-century wrought-iron column, discovered in India, and the girders and beams of the Orissa temples, rendered it necessary to exercise great caution as to the period at which iron was used in construction. Such magnificent efforts as those given were, however, not maintained, and no widespread or continuous records of the metallurgists' contributions to early constructive work could be presented. On the other hand, the civil engineer had, to quote the charter of the institution, "advanced mechanical science and directed the great sources of power in Nature for the use and convenience of man," for ages before the metallurgists rendered more than incidental service. As examples of great engineering works into the construction of which no metal entered, the lecturer referred to, and gave illustrations of, the primitive cantilever bridges of pine trees used to cross mountain torrents in Savoy. The interesting thirteenth century cantilever bridge made up of 20-foot beams given in the note-book of Villars de Honnecourt was also shown, as was a bascule bridge of the middle ages. The dome of Milan Cathedral, as designed by Leonardo da Vinci, the great Tuscan painter, engineer and architect, was also referred to as an example of a structure in which metal was not used. The employment of cast iron from the time of Queen Elizabeth to the present day was then dealt with, and the proposed cast-iron bridge of 600-foot single span, by Telford and Douglas, was referred to, and it was pointed out that in the nineteenth century metallurgists, by creating the age of steel, more than atoned for their somewhat tardy and intermittent efforts to supply engineers with suitable materials.

As regarded the use of cast iron and malleable iron, the influence of Watt in developing the steam-engine was traced, and it was admitted that the necessity for pumping water out of mines was the main factor in the evolution of the steam-engine, and, in turn, the development of British metallurgy of iron and steel dated from the time when the steam-engine of Watt enabled air to be readily pumped into the blast-furnace employed for the production of cast iron. It was then pointed out that more than half of the last century had elapsed before the "age of steel" began, and that towards the end of the century great attention was devoted to considerations connected with the molecular structure and properties of steel, and to enforcing the action of carbon, the element which gave steel its properties, by the addition of other elements than carbon in very small proportions. With regard to the slow growth of confidence in the qualities of steel, the opinion of successive presidents of the Institution, as expressed in their addresses, was quoted; Sir John Hawkshaw, Sir John Fowler, Sir Frederick Bramwell, Mr. W. H. Barlow, Lord Armstrong and Sir George Bruce being specially alluded to. In 1887, when Sir George Bruce delivered his address, the merits of steel had at last received recognition, and, as regards the crowning triumph of the age of steel—the Forth Bridge—Sir George exultingly exclaimed:—"At the Menai Bridge, the total quantity of iron was 11,468 tons; at the Forth Bridge, there will be 50,000 tons of steel and iron." No one had done more than Sir Benjamin Baker to insist on the importance of phenomena which engineers used to consider "mysterious" in connection with the behaviour of steel, and his warnings and example were at last being regarded and followed. The lecturer pointed out that when metallurgists gave engineers mild steel, they provided a cinder-free *solid solution* of iron and carbon. All subsequent advance had been due to the recognition of this fact, and to the gradual studies of the properties of metallic *solid* solutions. Sir John Hawkshaw, in his presidential address to the Institution, delivered in 1862, had said that if the strength of iron could be doubled, the advantages might be equal to the discovery of a new metal more valuable than iron had ever been. The lecturer contended that this was exactly what metallurgists had done with regard to steel. By suitable thermal treatment, and by suitable additions of comparatively rare metals, they had doubled the strength of steel as it was known in its early days. The nature of solid solutions was then explained, and the importance of allotropic modifications of iron was dwelt upon, this portion of the subject being illustrated by some difficult experiments. The question was then asked, could the past molecular history of a mass of steel be traced by microscopic examination of the solid metal? Some very beautiful experiments by M. Osmond, Mr. Stead, and others, were appealed to in evidence of the possibility of this. It was then demonstrated that solid metals might even reveal, by their structure, the vibrations to which they had been subjected, and Sir Benjamin Baker had constantly insisted on the importance of such vibrations. In making this clear, Vincent's experiments on the beautiful wave-structure that might be imparted to the surface of mercury by the aid of a vibrating tuning fork were then exhibited, and it was demonstrated that the surface of *solid* lead which had been subjected to similar vibrations possessed a similar structure to the vibrating surface of mercury.

Finally, with regard to the efforts metallurgists were making to study the influence of rare metals on iron and other metals, the reducing power of aluminium on metallic oxides was shown. Very high temperatures of 3000° C. and above were attained, and brilliant light was produced during the reduction of chromium, cobalt, nickel and other metals from their oxides.

In conclusion, the lecturer appealed to the new Alexander III. Bridge at Paris as showing the need for the careful measurement of high temperatures in connection with the treatment of large masses of steel. In the construction of the bridge, 2200 tons of *cast* steel had been employed, and a peculiar molecular structure was imparted to the steel by rapidly cooling it in air from a temperature of 1000° C. to 600° C.; this gave the metal certain mechanical properties which it would not otherwise have possessed. With reference to the aid given by metallurgists to engineers in connection with ordnance, reference was made to the address delivered by Mr. T. Hawksley, the father of the president, in 1872. He said that "In no way" other than by the study of such questions "could the Institution" of Civil Engineers "serve its country better, or better promote, in the interests of peace, the advancement of practical Science, and its application, if events should order, to the purposes of protective warfare." The use of copper, aluminium and other metals in electrical engineering was referred to, and the lecture ended with an appeal for the more extended study of the physical properties of metals.

THE GLACIERS OF KANGCHENJUNGA.

MR. DOUGLAS W. FRESHFIELD publishes, in the April number of the *Geographical Journal*, an account of his expedition to Kangchenjunga during the autumn of 1899. The Kangchenjunga group is cut off from the mountains of Nepal by the Khosi Valley on the west, and from the mountains of Bhotan by the Teesta Valley on the east. By crossing the lofty spur which unites it to the Thibetan highlands, it is just possible to get round the mountain without trenching on territory officially recognised as Thibetan. Mr. Freshfield's object was to make this high-level tour round Kangchenjunga, passing as near as possible to the great mountain, and, further, to obtain some accurate idea of the glacial features of the group. Progress was greatly interfered with during the earlier part of the journey by the storm which caused so much damage at Darjiling and by the lowering of the snow-line which resulted from it; but the tour was successfully accomplished, and from the head of the valley of the Kangchen, in Nepal, Europeans looked for the first time on the north-west face of Kangchenjunga, "not a sheer cliff like the three other aspects of the peak, but a superb pile of rock buttresses, terraces of snow and staircases of ice, through whose labyrinthine complexities the future conquerors of the mountain will have to find the least hazardous way to the

summit." Concerning the Kangchenjunga glaciers, Mr. Freshfield says, "Four glaciers radiate from the peak, pointing roughly to the north-east, south-east, north-west and south-west. Those are the Zemu Glacier, eighteen miles long, and the Talung Glacier, both draining to the Teesta, the Kangchen Glacier, fifteen miles long, and Yalung Glacier, both draining to the Arun and the Khosi. The forked spurs that protrude south and west from Kangchenjunga, dominated respectively by Kabru and Jannu, enclose in the first case the Alukthang glaciers, united not long ago in a single stream and now divided by little more than their moraines, and the southern glaciers of Kabru, which fall into a separate glen; in the second case, three considerable ice-streams, one of which almost meets the Kangchen Glacier at its lower extremity, the second builds across the valley, out of the rockfalls of the tremendous cliffs of Jannu which encompass its source, a remarkable wall of moraine stuff, similar to those of the Allalein, or the Brenva in the Alps, while a third fills a glen the stream from which joins the Kangchen torrent at Khunza."

Mr. Freshfield was accompanied by Prof. Garwood, Signor Vittorio Sella and his brother, and Mr. Dover, now road inspector at Sikhim, with an Alpine guide. Prof. Garwood devoted much labour to the compilation of a photo-topographic map of the region, which is to be published in an early number of the *Geographical Journal*, and is described by Mr. Freshfield as a "specimen of the right method to delineate glaciers." The paper is illustrated by a number of photographs taken by Prof. Garwood and Signor Sella. The specimen we reproduce represents Jannu and the dyke of the Jannu Glacier as seen from Kanbachen. The ice crosses the valley at right-angles, over a great dyke of moraine débris, and the torrent from the higher valleys is squeezed against the western hill. There was at one time a lake above the moraine dyke. The cause of the exceptionally large amount of moraine material is the great height and extent of the cliffs surrounding the head of the glacier. The glacier is now in retreat; the ice has sunk somewhat and the lateral moraines appear above it.

FIG 1.—Kanbachen in Nepal, with Jannu and the Dyke of the Jannu Glacier. (From the *Geographical Journal*.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE installation of the Prince of Wales as Chancellor of the University of Wales will take place at the University College, Bangor, on May 9.

LORD ROSEBERY has been formally nominated as Chancellor of the University of London, in succession to the late Lord Kimberley. As no other nomination has been made, he will be elected by Convocation at the meeting to be held on May 13.

THE London School Board, and the School Boards of most large towns, have for same years provided special schools where their pupil teachers receive instruction at specified times. It has now been decided that these schools are illegal. Mr. Cockerton, the Local Government auditor, has formally notified the London School Board that it has no authority in law to spend the rates in providing and maintaining special schools for the instruction of pupil teachers.

IN the House of Lords on Monday, in reply to a question by Lord Reay, referring to the new Regulations for Evening Schools, the Duke of Devonshire said:—"It is intended that all local expenditure by which is meant expenditure on evening schools other than that which is provided by Government grants—shall in future be provided by local authorities under the Technical Instruction Acts. As to whether the funds at the disposal of the local authorities will be sufficient for that purpose, the existing local authorities under the Technical Instruction Acts have by no means exhausted the funds at their disposal

which are applicable to the purposes of education. It is probable, however, that the responsibility for the whole of the evening school work, as contemplated by the regulations of the Board of Education for last year and this year, may involve them in an expenditure which their present resources are unable to meet. The Bill now before Parliament provides additional and, we believe, ample resources for all parts of the country except London. The present policy of the Board of Education is that evening schools, the great majority of which are intended for persons older than children, shall be provided and maintained by the local authorities for secondary education and receive grants under the regulations of the Board relating to secondary education."

SIR JOHN GORST spoke at Bradford on Saturday last upon the subject of the Education Bill of the Government. His remarks were aimed chiefly at the justification of the Government in making County and Borough Councils the local authorities for education. The necessity for this one authority in a particular sphere of influence has been almost universally accepted, but the difficulty is to determine the constitution of the body. Proceeding to describe the present position, Sir John Gorst said that the councils which are entrusted with technical instruction are entirely independent of central control. The consequence is that technical instruction as it is now carried out in this country is practically the entire creation of that new authority with very little assistance or direction from anybody. The councils are not bound to use the whisky money for technical instruction. They might have applied it to the relief of local rates, but in the last year for which statistics are available the total amount of the whisky money was 981,000*l.*, and of that sum 901,000*l.* was voluntarily devoted by the councils to technical instruction and only 80,000*l.* went to the relief of rates. Sir John Gorst remarked that the Duke of Devonshire and he selected the councils as the local authority rather than the School Boards, because a body which represented the ratepayers could not be a real local authority unless it had the absolute command of local finances, and if they had any other body levying rates without the consent of the body which properly represented the ratepayers they weakened the authority of the principal body and prevented it from gaining that proper influence over local affairs, expenditure and management which was essential to a properly constituted authority. A further question was whether the local authority was to be independent or to be tied down by the provisions of the statute. The effect of the working of the Technical Instruction Act was such as to be in favour of leaving these great local authorities to themselves. He preferred to trust them and give them ample powers, and leave them to exercise those powers for the benefit of the people whom they represented.

THE remarks made by Mr. Balfour at the Mansion House on April 23 upon the subject of commercial education are referred to in an article on the University of London which appears in another part of this issue. In the course of his address, Mr. Balfour said: "I would impress the doctrine, that important, necessary and essential as that narrow, technical training may be, we are ill learning the lesson of education which is now being taught us by other nations if we do not recognise that something more in the nature of general training and culture is absolutely necessary if we are to maintain the place so hardly won and so proudly maintained among the nations of the world. If commerce is to be treated as a subject of scientific study, it must not be approached simply in the spirit of those who desire to obtain a mastery of one particular instrument, one particular language, one particular form of knowledge, but must be approached, as all knowledge worthy the name should be approached, in the broader spirit of impartial scientific investigation. I do not think that higher praise can be given to the work in which Sir Albert Rollit and his colleagues are engaged than to say of it that, not merely have they given opportunities which would otherwise have been withheld to many persons in our community to learn the arts necessary for their work and success in life, but that they have also, and in addition to that merely technical training, in many cases laid the foundations on which may be built that solid and scientific knowledge of the commercial and economical forces of our time which are absolutely essential, as I think, to the proper conduct of the affairs of a great commercial country." Commercial education is so often understood to mean training in office routine that Mr. Balfour's statement as to what the term should imply ought to be widely known. All commercial and technical education of value must be founded upon sound primary and secondary education, and must be studied, not so much with the view of acquiring facility in carrying out the present duties of the office and workshop as with the intention to discover new methods and new processes. As with the individual, the nation that rests content with its achievements must eventually fall behind others which aim at obtaining and using new knowledge. It is in this spirit that commercial education must be viewed in order that it may assist national progress.

SCIENTIFIC SERIAL.

IN the *Journal of Botany* for April, H. W. Pugsley gives the first part of an article on the "British Capreolate Fumitories." Messrs. David Prain and Edmund Baker complete their "Notes on Indigofera." The various forms that have been included in the species *Indigofera tinctoria*, L., and *Indigofera Anil*, L., receive the fullest treatment, and the authors come to the following conclusions:—*I. tinctoria*, L., has been applied to three forms: (1) the wild form, which is probably indigenous to Africa; (2) the variety of the previous one, cultivated in southern India, at the present day more especially in Madras; (3) the plant cultivated in northern India, known as "Nil"; the differences between this and the other cultivated variety are so pronounced and constant that it seems justifiable to separate it off, when it becomes *I. sumatrana*, Gaertner. The specific name Anil, also given by Linnæus, is connected with the Egyptian vernacular word "Nil," which indicates any species that supplies the Indigo dye. In Egypt "Nil" would refer to *I. articulata*, Gouan, in India to *I. tinctoria*, L., while in neither of these countries would it include *I. Anil*, L., which will not grow in Egypt and does not find favour in southern India. De Candolle instituted three varieties of *I. Anil*, L., of which two call for comment. Var. α *oligophylla* is the same plant as *I. truxillensis*, H.B.K., which was probably cultivated in the West Indies in the time of Hans Sloane. Var. β. *polyphylla* is the plant now cultivated in the West Indies and other parts of the New World. This is the true *I. Anil*, L., but to avoid any confusion which may arise from the use of that specific name, it is suggested that it should be established, under another synonym, as *I. suffruticosa*, Miller. Arthur Bennett continues his "Notes on Potamogeton," and deals with some foreign species from Australia, America and Japan. The most interesting of four new British Hepaticæ described by S. M. Macvicar is *Aneura incurvata*. It comes near to *A. multifida* and *A. sinuata*. It may be expected to be recorded again, as it has been found in Austria, Germany and Scandinavia.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, April 25.—Prof. S. P. Thompson, president, in the chair.—Dr. Dawson Turner exhibited and described a mechanical break for induction-coils. The use of induction-coils in the production of Röntgen rays and in wireless telegraphy has made the construction of a suitable break a matter of importance. The ordinary break is unsuitable because o the wearing away at the point of contact, and there are objections to the use of mercurial breaks. The portable mechanical break which was shown by Dr. Dawson Turner consists of two metallic rollers with their axes parallel and kept in contact by a spring. One of the rollers has a cam attached to its spindle, and can be made to rotate by means of a small electric motor. Once in each revolution the cam separates the rollers, thus making the break, and at the same time causing the second roller, which rides loose upon its axis, to turn about one-eighth of a revolution. As soon as the cam has passed, the rollers are brought into contact by the spring, and the next break occurs at a different place. The wearing is thus distributed evenly over a large surface. The break is placed in a box containing alcohol or petroleum, and works best when rotating rapidly. An objection to the arrangement is the noise it makes when working. Some experiments were then shown on the discharge of electrified bodies by ultra-violet light. A disadvantage of the electric arc when used to furnish ultra-violet light for use in medicine

is that the light is accompanied by heat, so that it is necessary to shield the patient from the heat without interfering with the passage of the light. A condenser spark between iron electrodes is useful because it gives a large amount of ultra-violet radiation without much heat. Dr. Turner showed that this light is capable of discharging bodies whether positively or negatively electrified. He then showed that glass and mica are opaque to the radiation while pure rock salt is transparent.—Mr. Wilson Noble exhibited a mechanical break similar to the one already shown. A roller and a disc, with their axes parallel, are placed in contact and made to rotate in the same direction by a motor. Longitudinal slots are cut upon the surfaces of both, and the break occurs when a slot in the roller comes opposite a slot in the disc. Since the two are moving in opposite directions at their point of contact the break is very sudden. To vary the length of the break without altering the rate of rotation, the slot in the roller is wider at one end than the other, and the disc can be placed so as to touch the roller at any point of its length.—Mr. R. S. Whipple exhibited a temperature indicator for use with platinum thermometers, in which readings are automatically reduced to the gas scale. The instrument is very similar to the well-known Callendar and Griffiths' temperature indicator, with the exception that it is so arranged that the readings obtained are automatically reduced to the gas scale, thus avoiding the necessity of applying a correction. It consists of a simple Wheatstone's bridge with equal ratio arms, the other arms being the thermometer and a long helical bridge wire together with the compensating leads. A travelling contact is moved round the wire until a balance is obtained. The bridge wire is wound on an ebonite drum on the outer surface of which a helix has been cut. The contact piece, which is connected electrically with the galvanometer, is carried from the inside of a cylinder fixed to a shaft. A white celluloid tube on which the scale is divided is fixed to the outer surface of the cylinder. A screw of the same pitch as the helix on the ebonite drum is cut on the shaft, so that by rotating the shaft the contact is caused to travel along the bridge wire, and at the same time the scale is carried past an index placed above it. The scale has been so constructed that the reading at the index gives directly the temperature of the thermometer reduced to the gas scale. The instrument reads from 0° to 1400° C.—Mr. S. A. F. White read a note on the compound pendulum. In the determination of the length of the equivalent simple pendulum for a compound pendulum the form of which is a symmetrical bar and bob with one fixed, one movable knife-edge and no sliding weight it is convenient to make the mass of the movable knife-edge small. In this case, small displacements of this knife-edge will not materially alter the position of the centre of gravity or radius of gyration of the pendulum about an axis through its centre of gravity. The time of swing about the fixed knife-edge will therefore remain practically constant. The best determination of the correct position of the movable knife-edge for an equal time of oscillation will be given when for the smallest displacement of this knife-edge there is the greatest variation in the time of oscillation about it. The author has determined the position which makes $\frac{dt}{dh}$ a maximum, h being the distance of the axis of suspension from the centre of gravity. He has also drawn the curve showing the relation between $\frac{dt}{dh}$ and h. The calculations have then been applied to the determination of the position of the movable knife-edge in a particular pendulum. The experimental value of the ratio of h to k deduced from this pendulum when the movable knife-edge is adjusted to its right position agrees well with that predicted by the theory. The author states that when the length of the equivalent simple pendulum is about a metre, it should be possible with a stop-watch reading to 0·2 second to determine "g" to about ·1 or ·2 per cent. If the fixed knife-edge were made the movable knife-edge, the value of $\frac{dt}{dh}$ would be very large, but there would be difficulties in the way of measuring the small time of swing and the small equivalent length.

Chemical Society, April 17.—Prof. Tilden, F.R.S., in the chair.—Dimercurammonium nitrite and its haloid derivatives, by Dr. P. C. Rây. This salt was prepared by the addition of aqueous ammonia to a solution of sodio-mercuric nitrite. On solution in hydrochloric acid the new compound furnishes a mercuric ammonium chloride of the formula $2HgCl_2.NH_4Cl$, and with hydrobromic acid the corresponding bromide. These salts in turn, with sufficient potash, furnish respectively the chloride and bromide of dimercurammonium. The author's observations on these substances support the Rammelsberg-Pesci representation of the general structure of ammoniated-mercury salts.—Preparation and properties of 4-isopropyldihydroresorcinol, by Dr. Crossley. A correction in the nomenclature of this substance is made from 2:6-diketo-4-isopropylhexamethylene to that given above, since further investigation has shown that its usual structure is thereby better indicated.—Oxonium salts of fluoran and its derivatives, by Dr. Hewitt and Mr. Tervet. The authors have observed that fluoran and substances related to it, such as fluorescein, form salts with mineral acids, and of these the nitrate and sulphate of fluoran, chloride and sulphate of fluorescein and others have been prepared, analysed and described.—Influence of substitutions on the reactivity of the aromatic diamines, by Dr. G. S. Morgan. The author has studied particularly the influence exerted by the introduction of alkyl groups in various positions into the molecule of aromatic diamines on the reactivity of these substances with methylating agents.—The influence of certain acidic oxides on the specific rotations of lactic acid and potassium lactate, by Drs. Henderson and Prentice. It was found that antimonious oxide exerts no action on lactic acid and its potassium salt, and consequently has no influence of their rotations in solution. On the other hand, arsenious and boron oxides produce a change in the rotation of these substances which is greatest when they are present in quantity sufficient to form with the potassium salt compounds of the formulæ $(AsO) C_3H_4O_3K$ and $(BO) C_3H_4O_3K$ respectively.—The amounts of "ammonia" and "nitric" nitrogen and of chlorine in rain water collected at Rothamsted, by Dr. Miller. This paper gives the amounts of ammonia, nitrates and chlorine contained in Rothamsted rain water for each month from September 1888 to August 1901. The results show that the total nitrogen available to the soil from this source varied during this period from 3·31 to 4·43 lb. per acre per annum, the average being 3·84 lb., of which 1·8 lb. is secured during the winter and 2·03 lb. during the summer months. Of this total nitrogen, 70 per cent. is present as ammonia and 30 per cent. in the more easily available form of nitrates. Chlorine, on the other hand, is found in greatest quantity during the winter, the average content per annum for the period being 14·87 lb., of which 10·12 lb. is obtained during the winter season.—The amounts of nitrogen as nitrates and chlorine in the drainage through uncropped and unmanured land, by Dr. Miller. During the last twenty-four years—September 1877 to August 1901—the loss of nitrates in drainage water has been systematically investigated at Rothamsted, and this paper gives the results obtained. The average loss of nitrogen in this way amounts to 30 lb. per annum per acre, but varies greatly with the amount of rain and distribution of drainage. There appears to be also a considerable loss of lime. The average yearly amount of chlorine per acre in the drainage is about the same as that found in the rain, but wide differences occur occasionally. Drain gauges at a depth of 20 inches have during the last twenty-four years received on an average 7 lb. more chlorine than they have lost in drainage; the values for the 40-inch gauge are 17·5 lb. lost and 31·9 lb. received.—Benzylidenecamphoroxime, by Dr. M. O. Forster. The method of preparation, properties and behaviour towards reagents of this substance have been studied as part of a proposed systematic examination of substituted camphoroximes.

Linnean Society, April 3.—Prof. S. H. Vines, F.R.S., president, in the chair.—Mr. R. Morton Middleton exhibited two letters from Linnæus to Dr. David van Royen and Mr. Richard Warner, of Woodford, dated respectively April 18, 1769, and September 29, 1758, and also a letter from Sir J. E. Smith to N. Wallich on Nepalese plants, written in 1819.—Mr. R. A. Rolfe, on behalf of the Director, Royal Gardens, Kew, exhibited a series of specimens of *Pachira aquatica*, Aubl., and *P. insignis*, Savigny, from British Guiana, collected by the late G. S. Jenman, Government botanist, to illustrate the great variation which exists in the size and shape of the fruits. There was also a certain amount of variation in the leaves and flowers, though in the latter each species retained its own essential character. These trees were common over the great alluvial forest-region, extending also to Brazil, and were commonly cultivated for ornament.—On behalf of Mr. W. B. Hemsley,

F.R.S., Mr. Rolfe also exhibited some specimens illustrating the precocious germination of the seeds of a species of Dracæna. Germination had taken place through the pericarp while the berries were still hanging on the plant.—Mr. Spencer Moore read a paper entitled "A Contribution to the Composite Flora of Africa," in which he described a number of new species in the Herbarium of the British Museum. He found that the north-eastern tropics, especially British East Africa and the neighbouring parts of Somaliland and Southern Abyssinia, had yielded most of the novelties.—Prof. F. E. Weiss read a paper, illustrated by lantern-slides, on a biseriate halonial branch of *Lepidophloios fuliginosus*. The branch in question, about 7 in. in length, was found in a large nodule by Mr. George Wilde at Haugh Hill, near Stalybridge. Dr. Scott, in a preliminary communication to the British Association in 1898, had identified it with the plant described by Williamson as *Lepidodendron fuliginosum*, now generally included in the genus Lepidophloios. Prof. Weiss supported this identification, and brought forward several instances of halonial branches of Lepidophloios which possessed only two rows of tubercles, instead of the more usual quincuncial arrangement of the tubercles. The specimen referred to, and of which photographs were shown, were from the British and Manchester Museums, and instances were also cited from Williamson's published memoirs. The second part of the paper consisted of a detailed account of the anatomy of this well-preserved specimen, which went to confirm Dr. Scott's previous identification of it.

Geological Society, March 26.—Prof. Charles Lapworth, F.R.S., president, in the chair.—On a remarkable inlier among the Jurassic rocks of Sutherland and its bearing on the origin of the breccia-beds, by the Rev. J. F. Blake. On the coast of Sutherland due south of Port Gower is seen on the scars at low water a long rocky crest of Old Red Sandstone, with its flaggy beds dipping at a high angle. It is of considerable height, and is surrounded by nearly horizontal Jurassic beds containing large blocks of rocks similar to those of the crest, irregularly placed. The size, outline and relation to the surrounding rocks show that this cannot be a transported block, but must have been part of, or directly derived from, a neighbouring coast—like the modern sea-stacks of the present coast at Duncansby. From considerations of the character and distribution of the breccia-beds, it is concluded that they are the product of an ice-foot of Upper Jurassic age, which invaded the normal deposits of that period.—On a deep boring at Lyme Regis, by Mr. A. J. Jukes-Browne. During 1901 a boring was made near Lyme Regis in search of coal, and was carried to the depth of 1300 feet without reaching the base of the Upper Triassic Marls. The beds passed through were compared with those exposed along the cliffs from Lyme to Sidmouth. The author concludes that the boring did not reach the beds which near Sidmouth form a passage from the Keuper Marls to the Keuper Sandstones, and that the Keuper Marls proved by the boring are at least 1130 feet, and may amount to 1200 feet in thickness.

MANCHESTER.

Literary and Philosophical Society, April 15.—Mr. Charles Bailey, president, in the chair.—Dr. Henry Wilde, F.R.S., read a paper on the atomic weights and classification of the elementary gases, neon, argon, krypton and xenon. The recent determinations of the densities of the new gases by Prof. Ramsay and Dr. Travers prove conclusively that they belong to the seventh series of elements in Dr. Wilde's table, which includes nitrogen and the comparatively inert groups of the platinum metals. Within the limits of experimental error and residual interferences, all the members of this series are multiples of seven.—A paper on the hypnotic influence of prolonged vision of persistent motion and sparkling objects, by Mr. Thomas Kay, was read.—Mr. F. J. Faraday exhibited an old copy of Chateaubriand's "Atala," partly written in the huts of the American Indians in Louisiana and Florida during the author's first visit to the New World in 1789, and containing passages showing the continued existence amongst the Red Indians at the end of the eighteenth century of some of the religious beliefs and practices referred to in Mr. J. E. King's recent paper on the Jesuit records of 1611, noticeably with regard to the metempsychosis of the souls of infants, the exhuming of the bones of members of the family from the temporary village grave for reburial in a common national grave on the occasion of the "Feast of the Dead," or the "Feast of Souls," and the transporting of the bones of dead relatives during migration.—Prof. F. E. Weiss exhibited a specimen of *Welwitschia mirabilis*. This curious plant was discovered by Dr. Welwitsch in 1860 in the south-west of Africa, where it grows in very arid regions, rooted by a very long tap root. The upper part of the plant is protected by a very thick mantle of cork. It only possesses two leaves, which last throughout the life of a plant, being constantly renewed from the base, which lies protected in a groove of the stem. *Welwitschia* was first described by Sir Joseph Hooker, who considered it as belonging to the group of Gnetaceæ allied to the Conifers.

PARIS.

Academy of Sciences, April 21.—M. Bouquet de la Grye in the chair.—On some phenomena of voltaic polarisation, by M. Berthelot. Experiments on the polarisation effects of liquid cells, both with and without the addition of reducing agents.—On the methods of proving the electrolytic action of a battery, by M. Berthelot. An examination of the conditions under which the smallest possible quantity of gas set free in an electrolytic cell can be observed, together with some experiments in which formol instead of pyrogallol was used as the reducing agent.—On Abelian functions with complex multiplication, by M. G. Humbert.—The resistance due to companion waves, by M. de Bussy. The proportionality between the height of the companion waves and the square of the velocity of the vessel producing them was proved by three sets of experiments, on a model 1/16th natural scale, on the vessels *Guichen* and the American cruiser *Columbia*.—On Daniellia and their secreting apparatus, by M. L. Guignard. The existence of a secreting system distributed through the whole thickness of the wood is a characteristic feature of the Daniellia; with the Copaifera and the Eperua of tropical America, these are the only leguminous plants known possessing intraligneous secreting apparatus.—New observations on the fossil flora of the basin of Kousnetzk (Siberia), by M. R. Zeiller. The Permian flora of Siberia appear to be closely allied, at all events in the cases of the most abundant and characteristic species, with the normal Permian flora of Europe and North America, from which they are distinguished only by the presence of some particular types.—Observations of the sun, made at the Observatory of Lyons with the Brunner 16 cm. equatorial, during the third quarter of 1901, by M. J. Guillaume. The results are expressed in three tables, showing the number of spots, their distribution in latitude and the distribution of the faculæ in latitude respectively.—On the continuous deformation of surfaces, by M. G. Tzitzeica.—The laws of deformation, the principles of calculation, and rules for the scientific employment of mortars, by M. Rabut. It is shown that the mortar described is altered in shape when fired according to simple and precise laws, easily explained from the properties of the material. The laws resulting from these principles are in agreement with the methods of construction in practical use.—On a new method for the optical measurement of thicknesses, by M. Macé de Lépinay. A sketch of a new method is given which possesses the advantages of requiring no other reflecting surfaces than those of the plate studied, and of permiting exact measurements to be made even if the plate is not quite perfect from the point of view of homogeneity or parallelism of its surfaces.—On the absorption of radioactivity by liquids, by M. Th. Tommasina. Preliminary measurements of the absorptive power of various organic liquids for the radiation from radioactive substances are given.—On the formation of negative images by the action of certain vapours, by M. P. Vignon (see p. 13).—On a case of molecular rupture by bromine, by M. R. Fosse. In the reaction between naphthylol-dinaphthoxanthene and bromine, instead of the expected substitution by the halogen, a molecule of bromine is added on as with an unsaturated body, the trinaphthyl-methane molecule being then split up into a bromo-naphthol and bromo-methanal-1-naphthol-2.—On some derivatives of fumaric aldehyde, by M. R. Marquis. The acetin of nitrosuccinic aldehyde, the preparation of which is described in a previous paper, is decomposed by dilute acetic acid at 80° C. with formation of fumaric aldehyde, H.CO.CH = CH.CHO, the phenylhydrazone and oxime of which are described.—The transformation of new into stale bread, by M. L. Lindet. The amount of soluble dextrins in the crumb of bread as it leaves the oven amounts to more than 10 per cent. of the dry weight; this amount was found to decrease steadily on standing, until after four days there is only 2 per cent. The only alteration undergone by the crust is in the amount of water it contains.—On

the Fecampia, endoparasitic turbellaria, by MM. M. Caullery and F. Mesnil. The embryogeny of Fecampia is, on broad lines, similar to those described by Metchnikoff, Hallez and Jijima for certain Triclades and Rhabdoceles.—On a new type of Rhizocephalus, a parasite of the Alpheidæ, by M. H. Coutière.—Pathogenic and teratogenic actions, by M. Etienne Rabaud.—Some new attempts at experimental parthenogenesis in Amphibians, by M. E. Bataillon.—On the primitive form of crystallised bodies, by M. F. Wallerant.—On the geological constitution of the western Maroc, by M. S. Brives.—The recent discoveries of the Prince of Monaco at Baoussé-Roussé. A new type of human fossil, by M. R. Verneau. The cave known as the *Grotte des Enfants* has already yielded such valuable results in the hands of M. Rivière that the Prince of Monaco resolved to continue its exploration methodically. The most important result up to the present has been the discovery, at the depth of 7·75 metres, of a human skeleton of a new type, apparently negroid, for which the name of the Grimaldi type is suggested.—Researches on the experimental production of parasitic races of plants by harmful bacteria, by M. L. Lepoutre. Three abundant species of bacteria were studied—*B. fluorescens*, *B. mycoides* and *B. mesentericus vulgatus*—and attempts were made to infect the tubercles of potato plants grown under varying conditions.

DIARY OF SOCIETIES.

THURSDAY, MAY 1.

ROYAL SOCIETY, at 4.30.—Coefficients of the Cubical Expansion of Ice, Hydrated Salts, Solid Carbonic Acid, and other Substances at Low Temperatures: Prof. J. Dewar, F.R.S.—The Conditions determinative of Chemical Change and of Electrical Conduction in Gases, and of the Phenomena of Luminosity: Prof. H. E. Armstrong, F.R.S.—Contributions to a Theory of the Capillary Electrometer: I. The Insulation-Resistance of the Capillary Electrometer, and the Minimum Quantity of Electricity required to produce a Visible Excursion: G. J. Burch, F.R.S.

ROYAL INSTITUTION, at 3.—Recent Geological Discoveries: Dr. A. Smith Woodward, F.R.S.

LINNEAN SOCIETY, at 8.—(1) On the Mammalian Cerebellum, with special reference to the Lemurs; (2) On the Brain of the Elephant Shrew, *Macroscelides proboscideus*: Dr. Elliot Smith.—On the Early Condition of the Shoulder-Girdle in the Polyprotodont Marsupials, Dasyurus and Perameles: Dr. R. Brown.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Automatic Relay Translation for Long Submarine Cables: S. G. Brown.

RÖNTGEN SOCIETY, at 8.30.—The Relation between X-Rays and allied Phenomena in Light and Electricity: Ernest Payne. (*Discussion.*)

FRIDAY, MAY 2.

ROYAL INSTITUTION, at 9.—Experimental Researches on the Constitution of Crystals: A. E. Tutton, F.R.S.

MONDAY, MAY 5.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—On the mixed Carbides of Manganese and Calcium: J. S. Brame and Prof. Vivian B. Lewes.—Dangerous Chemical Substances: Oscar Guttmann.

SOCIETY OF ARTS, at 8.—Glass for Optical Instruments: Dr. R. T. Glazebrook, F.R.S.

VICTORIA INSTITUTE, at 4.30.—Procopins's African Monument of Joshua's Conquest of Canaan: Martin L. Rouse.

TUESDAY, MAY 6.

ZOOLOGICAL SOCIETY, at 8.30.—On the Mammals collected during the Whitaker Expedition to Tripoli: Oldfield Thomas, F.R.S.—The Wild Sheep of the Upper Ili Valley: R. Lydekker, F.R.S.—A List of the Fishes, Batrachians and Reptiles collected by Mr. J. ffolliott Darling in Mashonaland, with Descriptions of new Species: G. A. Boulenger, F.R.S.

SOCIETY OF ARTS, at 8.—The Printing of Modern Illustrated or Decorated Books: C. T. Jacobi.

WEDNESDAY, MAY 7.

ENTOMOLOGICAL SOCIETY, at 8.—On a new Cricket of Aquatic habits, found in Fiji by Prof. Gustave Gilson: Prof. L. C. Miall, F.R.S., and Prof. G. Gilson.—On the Lepidoptera of the Chatham Islands: Edward Meyrick.—On Asymmetry in the Males of Hemarid and other Sphinges: Dr. T. A. Chapman.

SOCIETY OF PUBLIC ANALYSTS, at 8.

IRON AND STEEL INSTITUTE, at 10.30 a.m.—Report of Council.—The Bessemer Gold Medal for 1902 will be presented to his Excellency F. A. Krupp, of Essen.—A selection of the following papers will be read and discussed:—Report by the Committee appointed to investigate the Nomenclature of Metallography.—On a New Vacuum Tuyere for Blast Furnaces: H. Allen.—On the Microstructure of Hardened Steel: Prof. J. O. Arnold and A. McWilliam.—On the Compression of Fuel before Coking: J. H. Darby.—On Gas from Wood for use in the Manufacture of Steel: J. Douglas.—On a combined Blast-Furnace and Open-Hearth Process: P. Eyermann.—On the Physical and Chemical properties of Carbon in the Hearth of the Blast-Furnace: W. J. Foster.—On the Sulphur contents of Slags and other Metallurgical Products: Baron H. von. Jüptner.—On the Elimination of Silicon in the Acid Open-Hearth Furnace: A. McWilliam and W. H. Hatfield.—Report on Research Work carried out during the past year: J. A. Mathews.—On the Iron Ore of Brazil: H. Kilburn Scott.—On the Recovery of By-products in Coking: J. Thiry.—On Brinell's researches on the influence of Chemical composition on the soundness of Steel Ingots: Axel Wahlberg.

AUSTRALIAN CHAMBER OF COMMERCE (Australian Club), at 4.—The Coal Resources of Australia: James Stirling.

SOCIETY OF ARTS, at 8.—Origin and History of Carriages: A. Chancellor.

THURSDAY, MAY 8.

IRON AND STEEL INSTITUTE, at 10.30 a.m.—A Selection of Papers from the list given under May 7 will be read and discussed.

ROYAL INSTITUTION, at 3.—Recent Geological Discoveries: Dr. A. Smith Woodward, F.R.S.

SOCIETY OF ARTS (Indian Section), at 4.30.—The Past and Present Connection of England with the Persian Gulf: T. J. Bennett.

MATHEMATICAL SOCIETY, at 5.30.—On Groups in which every two Conjugate Operations are Permutable: Prof. Burnside, F.R.S.—Fermat's Theorem on Binary Powers: H. E. Western.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Form of Model General Conditions. (Conclusion of Discussion).

FRIDAY, MAY 9.

COLD STORAGE AND ICE ASSOCIATION (Society of Arts), Afternoon.—The Rationale of Cooling Phenomena: Dr. W. Hampson.—The Business Side of Cold Storage: R. J. Key.

ROYAL INSTITUTION, at 9.—Exploration and Climbing in the Canadian Rocky Mountains: Prof. J. Norman Collie, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 8.

MALACOLOGICAL SOCIETY, at 8.

STONEHENGE.

The Wiltshire Archaeological and Natural History Magazine. Stonehenge and its Barrows. By William Long, M.A., F.S.A. Pp. 244; many illustrations. (1876.) Price 7*s.* 6*d.*

The Wiltshire Archaeological and Natural History Magazine. Stonehenge Bibliography Number. By W. Jerome Harrison. Pp. 170 (1902.) Price 5*s.* 6*d.*

THE Wiltshire Archæological and Natural History Society is to be warmly congratulated on its persistent and admirable efforts to do all in its power to enable the whole nation to learn about the venerable monuments of antiquity which it has practically taken under its scientific charge.

Chief among these, of course, is Stonehenge, and it is fortunate for students that while interest in this structure, unique in so many particulars, is being revived, such a rich mine of information as that supplied by the Wiltshire Society should be available.

It is within the knowledge of all interested in archæology that not long ago Sir Edmund Antrobus, the owner of Stonehenge, at the request of this famous local society, the Society for the Protection of Ancient Buildings and the Society of Antiquaries, enclosed the monument in order to preserve it from further wanton destruction, and with the skilled assistance of Messrs. Carruthers and Detmar Blow set upright the most important menhir, which threatened to fall or else break off at one of the cracks.

Ever since that time he has been the butt of agitations in the local parish councils, got up apparently by persons who care, not for the preservation of ancient monuments, but rather that there shall be no right of property in anything interesting enough to be worth chipping.

The "unclimbable wire fence" recommended by the societies in question, the Bishop of Bristol being the president of the Wiltshire Society at the time, is by them regarded as a suggestion that the property is not national, the fact being that the nation has not bought the property and that it has been private property for centuries.

It is curious to think that the very destruction of the monument is now urged as an argument against enclosure. The *Times* in a recent article tells us some of the arguments used before a Committee of the County Council.

> "There are old ways, long and systematically used, which lead directly to the stone circles, and the barbed wire stretches right across these ways. One fact alone is sufficient to prove their antiquity. The outermost circle of Stonehenge consists of an earth vallum worn down by time and weather, but still rising some feet above the natural surface of the ground. The ways in question cut through this vallum, which rises abruptly some three feet or so on either side of them."

Everybody except the devastators knows that this vallum is the equivalent of the temenos walls which surround the Egyptian temples, and is part and parcel of the temple.

It is very sad to read, both in Mr. Long's volume and the bibliography, of the devastation which has been allowed to go on for so many years and of the various forms it has taken. It appears that this temenos wall or vallum was the first to suffer by indiscriminate driving over it, so that its original importance has now become so obliterated that many do not notice it as part of the structure; and that it bears the same relation to the interior stone circle as the nave of St. Paul's does to the Lady Chapel.

It appears also, from the *Times* account of the meeting, that a recent paper by Mr. Penrose and myself on the orientation of Stonehenge may have added strength to one of the arguments so improperly employed and apparently endorsed by Mr. Shaw Lefevre and others:—

> "One fact of singular interest was elicited. There seems to have been a special gathering every year, numbering thousands of persons, at Stonehenge to witness the rising of the sun on the 21st of June. As Stonehenge, according to the best opinions, was originally constructed with reference to rites performed at this very moment, there is nothing extravagant in the supposition that there has been something in the nature of a public assembly on Salisbury Plain at midsummer ever since the circles of Stonehenge were first completed."

Meanwhile we trust the Wiltshire Society will continue its labours, which date back at least to 1866, for the preservation of the monument, and that the members of the various Councils concerned will read the literature the Society has printed and become less philistine in their attitude. If Stonehenge had been built in Italy or France or Germany, it would have been in charge of the State long ago. Let the County Council send a small committee to Carnac to see how the equivalent monuments are looked after there.

It is very sad that in this twentieth century there should be Englishmen philistine enough to wish to preserve a so-called "right of way" which cuts through the vallum twice and passes close by the most important and imposing stone circle in the world. It is still sadder that since Sir Edmund Antrobus, the present owner, has accepted the advice of the Societies I have named to enclose the monument, with a view to guard it from destruction and desecration, he has been assailed on all sides, as we have seen. The world of science has already one matter of the highest importance to thank him for, namely, the setting upright of the so-called leaning stone, which was tottering to its fall. Let us hope that before long the minor gaps in the vallum may also be filled up. When they are, the present upholders of the "right of way" through the major ones will be the first to insist that the road shall be deviated outside one of the most imposing monuments of the world. In the meantime, it is comforting to know that, thanks to what Sir Edmund Antrobus has done, no more stones will be stolen, or broken by sledge-hammers; that fires; that unskilled excavations such as were apparently the prime cause of the disastrous fall of one of the majestic trilithons in 1797; that litter, broken bottles and the like with which too many British sightseers mark their progress, besides much indecent desecration, are things of the past.

Let me now refer more particularly to the publications of the Wiltshire Society bearing on Stonehenge.

Dealing with Mr. Long's memoir first, it may be stated that it includes important extracts from notices of Stonehenge from the time of Henry of Huntingdon to Hoare (1812), and that all extant information was given touching on the questions by whom the stones were erected, whence they came and what was the object of the structure. The barrows on Salisbury Plain are next carefully described, and the information to be obtained from them discussed in a most masterly way. It is a very great pity that a book so full of facts of great interest along so many lines has no general index.

Many who have followed the recent work on the monuments will be glad to have beside them for ready reference so many extracts from the publications of those who have attempted to solve its mysteries in the past. Thus we learn (p. 44) that in 1771 Dr. John Smith, in a work entitled "Choir Gawr, the Grand Orrery of the Ancient Druids, called Stonehenge, Astronomically Explained, and proved to be a Temple for Observing the Motions of the Heavenly Bodies," wrote as follows:—

"From many and repeated visits I conceived it to be an astronomical temple; and from what I could recollect to have read of it, no author had as yet investigated its uses. Without an instrument or any assistance whatever, but White's 'Ephemeris,' I began my survey. I suspected the stone called *The Friar's Heel* to be the index that would disclose the uses of this structure; nor was I deceived. This stone stands in a right line with the centre of the temple, pointing to the north-east. I first drew a circle round the vallum of the ditch and divided it into 360 equal parts; and then a right line through the body of the temple to the Friar's Heel; at the intersection of these lines I reckoned the sun's greatest amplitude at the summer solstice, in this latitude, to be about 60 degrees, and fixed the eastern points accordingly. Pursuing this plan, I soon discovered the uses of all the detached stones, as well as those that formed the body of the temple."

With regard to this "Choir Gawr," translated Chorea Gigantum, Leland's opinion is quoted (p. 51) that we should read Choir vawr, the equivalent of which is Chorea nobilis or magna.

That the slaughter stone was once upright is rendered probable by a reference to Mr. Cunnington's digging in 1803 (p. 56). Mr. Long adds:—

"Mr. William Cunnington, F.G.S., informs the writer that if this stone *stood erect*, it must have entirely concealed the 'gnomon' from persons standing in front of the 'altar.' 'It would have been impossible,' he says, 'to see the sun rise over the "gnomon" from the exact centre of the building. It is nevertheless a fact that the gnomon *does* occupy this critical position, as to the sunrise at the solstice.'"

But as we now know that from the axis of the sarsen stones the sun did *not* rise over the "gnomon," that is the Friar's Heel, this reasoning is not conclusive.

Again, there is the question of the roof. In our paper communicated to the Royal Society, Mr. Penrose and myself gave reasons why the Naos, that is the space included in the horseshoe of trilithons, was covered. This suggestion, however, I now find is not new, the view having been held by no less an authority than Dr. Thurnham (p. 67), who apparently was led to it by the representations of the Scandinavian temples as covered and enclosed structures.

On pp. 71 *et sqq.* I find a very interesting extract from a paper by Mr. Cunnington on the "Geology of Stonehenge." He points out the origin of the sarsens according to Prestwich:—

"Among the *Lower Tertiaries* (the Eocene of Sir Charles Lyell), are certain sands and mottled clays, named by Mr. Prestwich the Woolwich and Reading beds, from their being largely developed at these places, and from these he proves the sarsens to have been derived; although they are seldom found *in situ*, owing to the destruction of the stratum to which they belonged. They are large *masses of sand concreted together* by a silicious cement, and when the looser portions of the stratum were washed away, the blocks of sandy rocks were left scattered over the surface of the ground.

"At Standen, near Hungerford, large masses of sarsen are found, consisting almost *entirely* of flints, formed into conglomerate with the sand. Flints are also common in some of the large stones forming the ancient temple of Avebury.

"The abundance of these remains, especially in some of the valleys of North Wilts, is very remarkable. Few persons who have not seen them can form an adequate idea of the extraordinary scene presented to the eye of the spectator, who standing on the brow of one of the hills near Clatford, sees stretching for miles before him, countless numbers of these enormous stones, occupying the middle of the valley, and winding like a mighty stream towards the south."

Mr. Cunnington displayed great acumen in dealing with the smaller stones not sarsens.

"The most important consideration connected with the smaller stones, and one which in its archæological bearing has been too much overlooked, is the fact of their having been brought from a great distance. I expressed an opinion on this subject in a lecture delivered at Devizes more than eighteen years ago, and I have been increasingly impressed with it since. I believe that these stones would not have been brought from such a distance to a spot where an abundance of building stones equally suitable in every respect already existed, unless some special or religious value had been attached to them. This goes far to prove that Stonehenge was *originally a temple*, and neither a *monument* raised to the memory of the dead, nor an astronomical calendar or almanac.

"It has been suggested that they were Danams, or the offerings of successive votaries. Would there in such case have been such uniformity of design or would they have been all alike of foreign materials? I would make one remark about the small impost of a trilithon of syenite, now lying prostrate within the circle. One writer has followed another in taking it for granted that there must have been a second, corresponding with it, on the opposite side. Of this there is neither proof nor record, not a trace of one having been seen by *any* person who has written on the subject. This small impost, not being of sarsen, but syenite, must have belonged to the original old circle; it may even have suggested to the builders of the present Stonehenge the idea of the large imposts and trilithons, with their tenons and mortices."

There are several references throughout Mr. Long's memoir to the tradition of the slaughter of Britons by the Saxons at Stonehenge, known as "The Treachery of the Long Knives"; according to some accounts, 460 British chieftains were killed while attending a banquet and conference. But one important item is omitted. I have gathered from Guest's "Mabinogion," vol. ii. p. 433, and Davies' "Mythology of the British Druids," p. 333, that the banquet took place on May eve "Meinvethydd."

There is ample astronomical evidence that arrangements were made for observing the sun on May day both before and after the erection of the sarsens, and I think by this the truth of the tradition is strengthened.

Of the more recently published volume dealing with the bibliography of Stonehenge it may be said that no reference to Stonehenge by any ancient author, or any letter to the *Times* for the last twenty years dealing with any question touching the monuments, seems to be omitted from the bibliography. Thus, to give an instance, I find my old friend Sir Arthur Helps' work on "Spain's Conquest of America" referred to because in vol. iii. he treated of sun worship in Peru. The bibliography is not only to be commended for its thoroughness, but for its admirable method; it is a model of what such a work should be, and has evidently been a labour of love: Mr. Harrison acknowledges his obligations to the Birmingham Free Reference Library and the Bodleian, as well as to the Society's library at Devizes.

NORMAN LOCKYER.

STUDIES IN THE DISTRIBUTION OF PLANTS.

Die Vegetation der Erde, Sammlung pflanzengeographischer Monographien. Herausgegeben von A. Engler und O. Drude. (Leipzig: Verlag von W. Engelmann.)

1. *Grundzüge der Pflanzenverbreitung auf d. iberische Halbinsel.* Von Moritz Willkomm. Mit 21 Textfiguren, 2 Helio und 2 Karten (1896.)
2. *Grundzüge d. Pflanzenverbreit. i. d. Karpathen.* Von F. Pax. Mit 9 Textfiguren, 3 Helio und 1 Karte (1898.)
3. *Grundzüge d. Pflanzenverbreit. i. d. Kaukasusländern, von der unteren Wolga ueb. d. Manytsch-Schneider, bis z. Scheitelfläche Hocharmeniens.* Von Dr. Gustav Radde. Mit 13 Textfiguren, 7 Helio und 3 Karten (1899)
4. *Die Vegetationsverhältnisse d. Illyrischen Länder.* Von Dr. Günther ritter Beck v. Mannagetta. Mit 6 Vollbildern, 18 Textfiguren und 2 Karten (1901.)
5. *Die Heide Norddeutschlands.* Von P. Graebner. Mit einer Karte (1901.)

THE editors of the series of which the five volumes before us form the first instalment are to be congratulated no less on the courage with which they have embarked on a vast undertaking than on the success which has thus far attended their labours. The authors who have been severally entrusted with the floras of the different regions have been wisely selected, and are well qualified by special knowledge, extending in some cases over a considerable number of years, to grapple successfully with a task of no small difficulty and one which calls for the exercise of critical judgment of no mean order.

The general method of treatment is, in its broader outlines, tolerably uniform throughout the series, though of course there is considerable diversity in the treatment of details. A brief historical introduction in each case gives an account of the previous work done in a particular region, and this is followed by a discussion of the physical characters and climate of the latter, in so far as these affect the nature of the vegetation and the distribution of the plants within the area. The floras themselves, though often containing rather lengthy lists of plants, are designed, in the first place, to give the reader a general picture of the vegetation as a whole, and also to enable him to trace its relations with the physical environment. For this purpose they are broken up into groups, characterised by the predominance of some particular tribe or assemblage of plants, *e.g.* the oak flora, the Mediterranean, the alpine, &c. In some cases, too, the cultivated plants are sufficiently described to give a fair impression of the chief features of the more inhabited regions. Perhaps the most generally interesting part of each book is that which deals with the affinities of the flora with the plants of foreign countries, and also the ecological peculiarities that are illustrated within the area of the several regions themselves.

The flora of Spain is discussed by Dr. Willkomm. It is one which is full of interest, not only from the large number of endemic species which it includes, but also for the great variety of *facies* which it exhibits. These characters are clearly traced in connection with the isolation, in the first place, of the peninsula itself, and, secondly, in the remarkable diversity of physical conditions which prevail within it.

The Carpathian flora, discussed by Prof. Pax, is one of remarkably mixed origin, but its affinities can be traced pretty definitely to a European source, on the one hand, and an Asiatic one on the other. Several forms from Siberia find a place here, but the greater number come from Asia Minor and do not extend farther into Europe. There is, of course, a fairly strong affinity with the flora of the Alps, whilst a Pyrenean element is also met with. The flora is thus rather a synthetic one, although there are a few endemic forms. The latter are, however, related to others occurring in the regions above named. In dealing with the flora of the lower slopes, the author deplores the mischievous effects of an imperfect acquaintance with the principles of forestry upon the woodlands, many of which are apparently suffering severely from ignorant treatment.

The volume is one which will appeal strongly to anyone who is interested in the broader problems of distribution and ecology, and it is a solid as well as a suggestive contribution to scientific literature.

Prof. Radde, in dealing with the plants of the Caucasus, describes the vegetation of the steppes to the north of the range, and his frequent journeys into these regions enable him to give a very fair impression of the appearance of these lands at different seasons of the year. The character of the vegetation of the higher altitudes of the Caucasus differs greatly on the two slopes, as might have been expected from the general trend of the mountains themselves. On the southern slope there is a great predominance of Persian plants, as shown by the abundance of species of Astragalus, Acantholimon and others. The prevailing character of the flora is markedly xerophytic, and it should be one which would repay further biological investigation.

The author distinguishes five principal zones, viz. the

steppes, woods, subalpine, alpine and high-alpine respectively, and these main subdivisions are broken up into smaller groups which exhibit some definite character by which they can be distinguished. A somewhat curious feature of the book rests in the inclusion of an account of the principal insect pests which are injurious to the cultivated plants.

The Illyrian flora, as described by Dr. Günther ritter Beck v. Mannagetta, is one which seems to be a promising, if difficult, field of exploration. The plants of the maritime regions are, for the most part, an extension of the typical Mediterranean vegetation; but in the higher levels, where the minimum temperature sinks below 14° C., it is succeeded by one of which the oaks form the characteristic feature. The swamp plants which occur in this zone consist, for the most part, of northern European forms, mixed with others of wide distribution. Still higher, the willows and pines form the distinctive land-marks, and these are finally succeeded by an alpine flora which varies in character in the different mountain groups. This is due largely to difference in geological character, and partly also to the isolation of the mountains themselves. The volume includes a short sketch of the Algæ of the Adriatic coast, and ends with a discussion as to the relationships of the Illyrian flora with that of the surrounding countries, especially with regard to the physical changes which have occurred since Tertiary times.

The last, but by no means the least interesting, volume, by Dr. Graebner, deals with a more restricted formation, but this very circumstance affords an opportunity for a more detailed treatment. The heath and moorland vegetation is one which fairly bristles with interesting problems, and the volume in question forms a useful contribution to the whole subject. Here and there, perhaps, the chemical aspects of the relation between plant and soil preponderate over the hardly less important biological ones. The author corrects a common error as to the relation between the heather and a limestone soil. He shows that the destruction of the heather, or its non-appearance, is not due to the presence of the calcium salts directly, for he proves by experiment that in a sufficiently poor soil lime may be added in quantity without any injury to the plants in question. But a natural limestone soil is commonly also rich in other mineral constituents which are available for food manufacture, and it is to the presence of these that its absence or extermination is due. Heather is, in fact, very sensitive to manure, which causes its disappearance from soils which may have been previously infested by it.

It is, of course, quite impossible to do justice to the books under consideration within the limits of a short notice such as the present, but it is hoped that enough has been said to indicate their importance in helping to fill a serious gap in botanical literature.

It may be fairly said, moreover, that each volume will be quite indispensable to anybody who may desire to make a close acquaintance with the scientific aspects of the floras of the regions thus severally dealt with. And, taken collectively, they render it possible to acquire a far more intelligent grasp of the facts, and therefore also of the problems, of plant distribution and ecology than has hitherto been practicable for most of us.

OUR BOOK SHELF.

La Question de l'Eau potable devant les Municipalités. By P. Guichard. Pp. 190. "Encyclopédie Scientifique des Aide-Mémoire." (Paris: Gauthier-Villars, n.d.) Price fr. 3.

IN this work the author has brought together accounts of the water supplies of some twenty-six towns of France, giving details, as far as possible, of the source from which the water is derived in each case, of the treatment to which it is subjected before distribution and of its chemical and bacteriological character. These accounts are derived from analyses and reports furnished by the various analysts who have actually examined the supplies, and are of very varying degrees of completeness. The object which the author had in view in making his inquiries was to ascertain what method of purification, if any, was usually employed by the municipality to ensure the freedom of the water from the germs of disease. The answer to this question is that the municipalities select the best water at their disposal and deliver it to the consumers either without any treatment or after filtration through sand, Anderson's iron process being used in a few cases. The author does not regard sand-filtration as by any means a satisfactory method of purification, in spite of the fact that experiments have shown that when properly carried out it is extremely efficacious, and that the comparative freedom from water-borne disease of towns like London, which make use of water known to be polluted, depends entirely on its use. No discussion of this or kindred points is given, and this somewhat detracts from the value of the book. After pointing out the numerous sources of contamination which may affect the water of towns both before collection and during distribution, the author recommends all householders to protect themselves by purifying all water in their own houses by filtration or other means, and believes that only in this way can security be attained. A very proper and timely protest is made against the continued use of cemeteries for burying those who have died of infectious diseases, and also against the fashionable institution of cemeteries for pet animals, the infiltrations from all of which pass into the streams and rivers of the district, so that, as the author expresses it, "nous mangeons ou buvons de l'homme et du chien à une sauce non prévue dans les traités de gastronomie."

Plissements et Dislocations de l'écorce terrestre en Grèce By Ph. Negris. Pp. 210; 2 maps. (Athens: C. Beck; Paris: C. Béranger, 1901.)

THE large questions raised by the author cannot be adequately discussed in a brief notice, so it must suffice to state his main facts and inferences, expressing doubts in passing. Since Jurassic times, successive earth-movements have affected Greece and the adjacent parts of Turkey. The foldings produced are distinguished by local names. The earliest, or Olympic, which is pre-Cretaceous, runs from N.W. to S.E. along the eastern coast and a chain of islands as far as Karpalho. The Pentelic, closing that period, is at right-angles to it and acts more especially on the Ægean area, its western coasts and the Morea. The Achaic, which occurred during the Eocene, more or less affects the whole region and even Crete, running W.N.W. to E.S.E. The Pindic, closing the Eocene, trends in a N.N.W.-S.S.E. direction and can be traced in the Pindus mountains, the country to the west and the Morea. Last is the Tenarus folding, which began late in the Pliocene and affected the whole of the Greek kingdom, running from N. to S. All are generally associated with outbursts of igneous rock—peridotite (serpentine) in the earlier, trachyte in the later. There are also three important sets of faults, on which, however, we cannot dwell. The Tenarus folding pro-

duces the most important effects, for the author regards it as only a part of a great series of disturbances which modified the earth's crust as far away as the American continent. These are mainly responsible for the Glacial epoch, and the advance or retreat of the ice and the variations in sea-level must be attributed to earth-movements during it. Often, he insists, the sea, rather than the land, has altered its level, owing to changes in the form of the ocean basins. No doubt this is true, but we think the author presses it too far. He has also such faith in land-ice as to introduce the Scandinavian ice-sheet to the Shetland Isles, without caring to explain how it got across the deep valley which contours the southern and western coast of Norway. The earth-movements already mentioned were sometimes rapid, and the author connects the later of them with traditional deluges. The fabled Atlantis is Brazil, which had been converted into an insular tract by a rise of the sea. All this is certainly ingenious, though it may be unconvincing. He also gives us an explanation of the curious "bone beds" of Pikermi. Downward movements (connected with the second set of faults) submerged the lowlands. The animals fled for refuge to the hills, where they were killed *en masse* by mephitic vapours, which, fortunately for geologists, were exhaled in the nick of time, and their dead bodies were afterwards carried lower down by floods and mudstreams. *Credat Judæus!*

Last Words on Materialism. By L. Büchner. Translated by J. McCabe. Pp. xxxiv + 299. (London: Watts and Co., 1901.) Price 6*s*. net.

IT can scarcely have been the intrinsic worth of these occasional essays which induced the "Rationalist Press Association" to circulate them in an English dress. The volume is marked by all the confident dogmatism and loose reasoning for which the author of "Force and Matter" is unfavourably known to serious students. Its value as a contribution to genuine thought on the ultimate constitution of the world around is of the slightest. The author's position is that thought and will are secondary derivatives of a reality which is, in its own nature, "material" in the sense of being not mental, but for this position no proof whatever is offered. The "idealist," who comes in for a good deal of abuse which, from an English point of view, must be pronounced decidedly undignified, is never fairly met. His real argument, that the physical world itself is only given us in terms of the experiences of a sentient perceiver, is quietly ignored, and he is only allowed to make the futile objection that he does not know by what special process physical energy is "transformed" into consciousness. The writer's competence in philosophic discussion is shown by the fact that he thinks the inability of savages to count beyond four a proof that mathematical science is purely empirical. Similarly, he thinks Kant's view of the presence of an *a priori* element in knowledge refuted by the irrelevant appeal to the fact that knowledge has been acquired by a process of gradual development. The real point has, of course, nothing to do with the process by which we come to know; it is purely a question of how knowledge is constituted when you have got it. The excursions into philosophic history made in such essays as those on "Hobbes" and on "Buddhism and Christianity" are even sorrier stuff than the rest of the book. Büchner seems to have known little or nothing about the subject; he repeats complacently the absurd farrago by which Pythagoras has been brought into connection with Buddha, and expressly praises Hobbes for being—precisely what he was not—an empiricist. The "Rationalist Press Association" is doing scientific thought no good service in issuing such a mixture of anti-ecclesiastical rhetoric and crass metaphysical dogmatism as representing the views of serious science about the world.

A. E. T.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Misuse of Coal.

WHILE most thoroughly agreeing with Prof. Perry in his desire to see a more efficient use made of our coal-supply, I yet think that he has drawn far too gloomy a picture of the future, and I wish to draw attention to a consideration which does not seem to have been present in his mind, or to have occurred to any of those hitherto dealing with the question as either authors or inventors. Prof. Perry says that "scientific men know of no other store of energy available for man's use than fuel from the earth, except what we may get by the help of the tides or by the wind or waterfalls." With the exception of the tides, the energy of all these sources is derived ultimately, as is also that of coal itself, from the heat radiated by the sun, and what I wish to point out is that the heat of the sun may be made to furnish power in quite another way—a way, in fact, indicated by Nature herself.

Prof. Perry points to animal organisms as types of efficient engines. Now, what is the fuel consumed by these engines? Obviously it is *vegetable matter* which derives its energy from the *solar radiation of the present day.* At the same time, it is evident that at the present moment only a small percentage of the solar radiation falling on the surface of the earth is used in this way; yet it will be found that the amount of energy derived from this source is very large compared with that provided by our coal-supply. The detailed calculation cannot be attempted here, but a few figures will serve to show the order of magnitude we are dealing with. Taking Prof. Perry's figure for a year's coal-consumption at 663 million tons, and taking the average efficiency of engines at 3 lb. of coal per horse-power hour—which is probably too high an efficiency—the figures work out to an annual output of 495,000 million horse-power hours, and this is roughly equivalent to 56 million horse-power working continuously night and day. Considering the number of human beings, horses, cattle and sheep, and considering their output in heat as well as in mechanical work, it is evident that the energy supplied by food—however efficiently used—must be vastly greater than that given by our present coal-consumption. Here, then, is an enormous source of energy only partially tapped at present—the heat radiated to the earth by the sun—and the method of using it is indicated by Nature. When our stock of fuel approaches exhaustion, we shall—so it appears to me—have to set to work and—to put it crudely—grow our own fuel as we go along.

The use of vegetable matter for fuel is by no means unknown even to-day; for although wood has long ceased to compete with coal as a fuel, yet in Germany at the present time a new industry is growing up in the production of crude spirit from potatoes. This spirit is used as a *cheap fuel* in internal-combustion motors, and is therefore evidently able to compete with earth-fuels even in a northern country where solar radiation is not very intense and land-values are high. The progress from the use of wood and charcoal as a fuel to the use of potato-spirit is so great that we may reasonably expect much more in the same direction when once attention has been concentrated upon the matter. In fact, it may not be too much to expect that ultimately the regeneration of carbon from the dioxide of the atmosphere may be accomplished by means of synthetically prepared bodies which—somewhat like the chlorophyll of the living plant—are capable of decomposing carbon dioxide under the influence of sunlight. In those circumstances, the solar heat used in the evaporation essential to the growth of plants might be saved for the direct production of fuel, and the yield per acre of sunlit area greatly increased. I think, therefore, that in "fuel farming," in the first instance by the most prolific plants available, and ultimately by purely chemical agents, the problem of the supply of energy after the exhaustion of the world's coal-supply may perhaps be solved. All I am here trying to show is that the quantity of energy available by these means is large compared with the power actually in use at the present day, and even this I have only indicated in the roughest way; but I agree with Prof. Perry as to the extreme importance of the question, and I think with him that it is a matter of vital national importance. If, however, fuel farming is really a

possibility of the future, then perhaps Prof. Perry's gloomy picture of the decay of Great Britain may be falsified. The place of our coal-mines in our national assets would then be taken by the vast areas of sunlit land in our Colonial Empire, for fuel-production would then become a question of the number of acre-hours of sunlight available.

I should like to add that what I have said in this letter does not at all lessen the urgency of Prof. Perry's plea for efficient engines; in fact, I think that what I have pointed out tends to strengthen the demand for a great national effort at the solution of these pressing problems. At present we are, in matters of energy, "robbing posterity" while it is eminently desirable that we should discover a way—if there be one—of "paying our way," and I think that in fuel farming such a way may perhaps be found. WALTER ROSENHAIN.

443 Gillott Road, Edgbaston, April 27.

MR. ROSENHAIN is mistaken as to the ignorance of inventors; many engines have been invented and referred to in newspapers during the last thirty years for utilising solar heat. I may remark that such heat engines may be very efficient, because the available temperature may be very high indeed. I have sometimes wondered why metallurgists neglected the possibility of obtaining very high temperature furnaces from the heat of the sun. As to the energy available, at p. 14 of my book on "Steam" I say:—"On one square foot of Egypt the heat energy received in one year from the sun is about 10^9 foot pounds, or 500 horse-power hours." This is nearly equivalent to the energy of a coating of coal all over Egypt one foot thick, and promises a future for the Sahara and other cloudless regions of the earth. I therefore admit that I did not give sufficient weight to this consideration of the direct heat from the sun, and I am very glad that Mr. Rosenhain has drawn attention to my neglect.

J. PERRY.

Experimental Mathematics.

PROF. PERRY's syllabus in practical mathematics has now been published two or three years, and the results of actual experience of its working may have some interest. We have in this institute about three hundred students of mathematics, including boys in the day school as well as older evening students, who follow a course on the lines of Prof. Perry's syllabus, and in both classes the adoption of the method has aroused an increased interest in the subject. This increase of interest seems to be due to the fact that the method is essentially experimental as well as deductive. Mathematics is treated as a science rather than, according to a common tradition, as an "arts" subject. The student is taught to investigate the facts for himself by experiment in the form of actual plotting and measurement and numerical calculation, just as in the study of such a science as electricity he investigates a law for himself in the laboratory and, usually at a later stage, proves in his theoretical work that that law follows from his previous knowledge. This is not merely a question of illustrating elementary geometry, but the practice may be carried with advantage into what are usually considered quite advanced parts of his work. However well a student may know the analytical proofs involved, he greatly improves the firmness of his grasp by actually plotting, with various numerical values of the constants, curves to represent such a case, for instance, as the small oscillations of a stiff spring, or the form of a bent beam. In pure mathematics, especially in differential geometry, many examples may be found, and, in fact, the method of conformal representation, which has been so fruitful in the theory of functions and its applications, is really an instance of this method. Besides increasing the average student's interest in his work, these "direct vision" methods, used systematically throughout a student's course, give more solidity and a clearer definition to his ideas than it seems possible to attain by abstract reasoning alone.

My special object, however, in writing is to insist on the value of the method as a logical training. We sometimes hear of the "invaluable logical training" of Euclid with the implied assumption that other methods of treating mathematics are illogical. This view seems to ignore the fact that there is an inductive as well as a deductive logic. If a boy is taught from the beginning to verify all theorems by actual plotting and measurement, he trains, not only his logical powers of deductive reasoning in proving his theorem from its premises, but also his equally logical powers of inductive reasoning from observation and experiment. From the point of view of educational theory this seems a sounder method than to restrict his training to one form of logical reasoning to the neglect of the other. The deductive logic of the syllogism was the only form known in the time of Euclid, but it is scarcely necessary to say that inductive logic now holds a recognised place, and the whole development of modern experimental science has proceeded by its methods.

John Stuart Mill, as is well known, devotes a very scanty consideration to syllogistic reasoning on the ground that "Formal Logic therefore, which . . . have represented as the whole of logic properly so called, is really a very subordinate part of it, not being directly concerned with the process of Reasoning or Inference in the sense in which that process is a part of the Investigation of Truth," and that "The foundation of all sciences, even demonstrative or deductive sciences, is induction."

This may, perhaps, be the explanation of the difficulty which so many boys as well as older students feel in comprehending demonstrative geometry. Most teachers of evening students have met with men of considerable ability and some maturity of mind who have little or no difficulty with algebraical work, but can never comprehend the meaning of a proposition in Euclid. The syllogistic method of reasoning seems to find no avenue into their minds, although they can reason well enough from observed facts. Such people are usually set aside as having no mathematical gift, but all must have notions of space and time, and consequently of change and a rate of change, and if rigid deductive methods were so essential as is often supposed to the science which puts those notions into scientific form, they would scarcely be incomprehensible to so many. If anyone has the power of comprehending the facts of a science such as chemistry, he must have some power of putting that knowledge into scientific form, and so anyone whose experience is given in space and time can scarcely be quite without the power of understanding the science which deals with those conditions of his experience. In fact, if students who seem to be without mathematical power are allowed to approach the subject by an experimental method, they find no difficulty in understanding it and may in time come to grasp the significance of deductive methods. In secondary schools of the classical and mathematical type, boys who are not on the science side are at present almost without the opportunity of developing their inductive logical powers, with the exception of the few who reach the stage where they can draw their own conclusions from the facts of philology or history. Experimental mathematics might in this case be made to supply the place of the missing experimental training.

However one may admire the symmetry of an ideal rigid body of mathematical knowledge, built up in the mind of the learner so that each step is made to depend by flawless abstract reasoning on what has gone before, and so on down to necessary axioms at the foundations, such a process cannot be carried out in the practice of education. It is sometimes said that a student should not be allowed to use any process or to believe any theorem until he can render a complete and perfect reason for it. But if a student is to follow such a method he should not be allowed to use $0\dot{3}$, until he can justify his use of it from a knowledge of the meaning of a limiting value and of the criteria for the convergency of series, nor may he use $\sqrt{2}$ as a number until he has mastered the modern theory of irrational numbers and made up his mind whether to hold opinion with Dedekind and Weierstrass, that the conception of an irrational number is to be based on a purely arithmetical theory, or with Du Bois-Reymond, that it is essentially geometrical and inseparably connected with linear magnitude. It is obvious that no teacher can attempt such a course; these difficulties are always passed over without proof.

In the method of practical mathematics, this practice is frankly recognised as legitimate and natural, and is systematically extended to other parts of mathematics.

Whatever may be true of the superstructure, the fundamental notions of pure mathematics have not been built up by strict deductive process, but by a series of successive approximations to the truth. The conception of a limiting value is a case in point. Until the time of Cauchy, the existence of a limiting value was thought to be self-evident on geometrical grounds in such a case as that of the area of a polygon inscribed in a circle. Cauchy in his treatment of definite integrals recognised that it was necessary to prove that a definite limiting value existed in such a case, but it was only in 1883 that a completely neces-

sary and sufficient criterion for the existence of a definite integral was supplied by Cantor and Dedekind.

Thus the great body of analysis had been built up long before the fundamental notion of a limit was completely established.

A somewhat similar course might be traced in the development of modern ideas as to the basis of mechanics.

In Prof. Perry's method, especially in teaching the calculus, it is recognised that this is the natural way to approach the subject, not only for the science as a whole, but in the mind of the individual student, and its foundations are soundly laid on direct geometrical intuition and the notion of a rate of increase, full analytical treatment being left to a much later stage.

This enables the calculus to be introduced at a much earlier stage than usual, and I may here quote the graphic advice of Prof. Burkhardt, all the more striking as it comes from a mathematician distinguished in pure mathematics:—"Dem angehenden Jünger der Mathematik würde ich raten, sogleich mit beiden Füssen in die Differential- und Integralrechnung zu springen."

F. M. SAXELBY.

Royal Technical Institute, Salford.

Rearrangement of Euclid's Propositions.

I FEEL that Prof. Lodge's proposal to change the order of Euclid Book I., 1–32, is the real solution of the present problem of the teaching of elementary geometry. The budding engineer has his practical mathematics, the embryo wrangler will absorb geometrical truths served up in almost any manner; but the ninety per cent. to whom mathematics is a mere mental training must have their work put before them in an interesting, practical and yet logical manner. I should, however, like to put forward the following three points:—

(*a*) That Prof. Lodge's idea should be carried further, and Euclid, Books I.–VI., divided into four new books, as:—

The straight line	— Euclid I. 1–32 in some good order.
The circle	— Euclid III. 1–34, IV. 1–5 and escribed circles.
Areas	— Euclid I. 35–48, II., III. 35, 36, 37, IV. 6 to end.
Proportion	— Euclid V. and VI.

For Book I., I would suggest an order commencing with I. 32, cor. 2, which is the most general proposition for all rectilinear figures; and also that certain well-accepted riders should be added, many of which form more powerful instruments for solving geometrical problems than the majority of Euclid's propositions; that, in the circle, tangents should be treated as limiting chords; that, in areas, the "alternative" proofs of Euclid Book II. should be *the* proofs; finally, that proportion be done semi-algebraically, using fractional notation $\frac{AB}{CD}$.

(*b*) That it is not necessary—I may say, not advisable—to teach a beginner the words of a strict definition; but he should be given the idea alone, built up from practical use of a set of instruments, the verbal definition following when he is able to appreciate it. I would advocate that the following definitions be substituted for Euclid's unsatisfactory ones.

A straight line is one such that if any part be taken up and applied to any other part *in any manner*, so that its extremities fall on that part, it will coincide altogether.

The angle—the trigonometrical definition.

Parallel straight lines—the converse of axiom XII.

These would lead, for the student, to the ideas that a straight line can be drawn with a *ruler*, an angle drawn or measured with a *protractor*, and parallel straight lines drawn with two *set-squares*, one fixed and the other movable.

If these were accepted, I. 13, 14, 15, 27, 28, 29 follow almost axiomatically, and we are enabled to prove I. 32, cor. 2, by a supposititious construction, obviating such practical proofs as "walking round the sides" or Prof. Minchin's better idea of placing a pin along a side and moving it round, substituting a purely geometrical proof.

(*c*) That it is unreasonable to bar supposititious proof-constructions—*e.g.* in the bisector proof of I. 5. For no exception is taken to the particular enunciations of I. 4 or I. 8, although at that stage we are unable to *draw* one triangle with its parts equal to those of the other.

The Sweet Briar as a Goat Exterminator.

THE introduction of the sweet briar into Australia, in many parts of which it is naturalised, affords a striking illustration of the mode in which the balance of nature may be disturbed in a wholly unforeseen way.

The fruit of the sweetbriar consists of a fleshy receptacle lined with silky hairs which contains the seed-like carpels.

I extract from the *Agricultural Gazette of New South Wales*, vol. xiii., No. 3, March, 1902, p. 313, the following note by Mr. E. A. Weston, a well-known veterinary surgeon of Launceston, Tasmania:—

"With reference to *Rosa rubiginosa*, I thought it might interest you to know that the hairy linings of the fruit caused the death of a number of goats here by forming hairy calculi, which mechanically occluded the lumen of the bowels. These goats were put on the land with the idea that they would eat down the briars and ultimately eradicate them, but the briars came out best and eradicated the goats. The cattle running on the land are also very fond of the briar berries, and from time to time one will die, and on *post-mortem* no pathological changes can be found in any of the organs, nor do the hairy calculi appear in them, although their various stomachs are one mass of the briar seeds."

Kew. W. T. THISELTON-DYER.

Stopping down the Lens of the Human Eye.

IN photography, if the lens is affected with spherical aberration or other defects, or if the aperture is too large for good definition, the operator usually gets over the difficulty by using a smaller aperture or stop. This improves the definition and makes the picture sharp even to the corners of the plate. This process is technically called "stopping down the lens." In amateur landscape work I generally use an aperture or stop with a diameter of one-fiftieth of the focal length of the lens, or $f/50$.

But the human eye has defects, especially as we get old. For instance, the curvature of the crystalline lens becomes too flat, &c., and we have to use spectacles to enable us to read. Reasoning by analogy, diminishing the aperture of the eye by "stopping down the lens" ought to improve defective definition and make the vision sharper, and experiment proves that such is actually the fact. I find that the best effect is obtained by holding a thin metal plate close to the eye, with an aperture in it one-fiftieth of an inch in diameter. This arrangement resembles the old single landscape lens used in photography. The small stop is in front, the lens in the middle and the sensitive plate or retina at the back. I use convex spectacles myself for reading, but with a stop of that size I can easily read small print within 4 inches of the eye (or even less) in a good light without spectacles. I have tried the experiment with several of my elderly friends, and in every case with success. Anyone can try the experiment by means of a pinhole in a card.

I do not know exactly what is the focal length of the lens of the human eye, but supposing it to be half an inch, then with a stop of one-fiftieth of an inch the technical expression for the size of the stop would be $f/25$, or double the diameter of the one I use in landscape photography. I enclose a metal disc with such an aperture. By looking through it I can read the smallest type in NATURE at 4 inches from the eye.

WM. ANDREWS.

Steeple Croft, Coventry, April 25.

Prisms and Plates for Showing Dichromatism.

DICHROMATISM, or the change of colour of an absorbing medium with increasing thickness, is usually shown with plates of coloured glass. It is not always easy to obtain the right kind of glass, and only a few of the aniline dyes are suitable for the purpose. The medium should transmit two distinct regions of the spectrum, the absorption coefficient for one being greater than for the other. I have found that it is better to give the medium the form of a prism, for then the transmitted colours are separated, and the more rapid fading of one as the eye is moved from the refracting edge to the base can be followed. A number of years ago I found a small amount of an unlabeled dye which transmitted a red band and a green band, that is, it had a strong absorption band in the yellow and the blue. Thin layers of this dye were bright green, thick layers were blood red. I have never been able to find the dye again, though I have examined a large number of dyes, but I have found that a mixture of commercial "brilliant green" with a little naphthol yellow has

identical optical properties. Brilliant green alone in thin layers is blue rather than green, and though it shows dichromatism, the change from blue to red is not nearly so striking as a change from green to red. The prisms can be made in the following way.

A quantity of Canada balsam is boiled in an evaporating dish until a drop placed on a cold surface becomes quite hard. The dye must not be added until the balsam has cooled almost to the point of becoming thick, otherwise it will be decomposed and a very muddy green result.

Enough brilliant green must be dissolved in the balsam to make it appear deep red in layers 1·5 cm. thick. Thin layers will be found to be blue. The naphthol yellow is now added in quantity sufficient to change the tint of thin layers from blue to green. Possibly some samples of the dye will not require the addition of the yellow, but all which I have tried are improved by the process. A hollow prism is now made by fastening two pieces of thin plate glass between two grooved strips of wood. The base of the prism should be about 2 cm. thick if the strips of glass are 4 cm. long. The plates are warmed with a flame and the coloured balsam poured between them. After the balsam has cooled it is a good plan to run a quantity of melted sealing-wax upon the top of it, which strengthens the prism. An incandescent lamp or gas flame viewed through the prism is seen divided into a green and a red image, the former gradually fading away as the eye is moved towards the base of the prism.

If a larger amount of the colouring matter be added to the balsam and the fluid be pressed out between pieces of plate glass, screens can be made which transmit a very good secondary yellow. Through these screens a sodium flame is absolutely invisible, though a gas flame appears of a colour very closely resembling the soda flame in tint. The colour of the transmitted light depends also on the original composition of the light. By a suitable adjustment of the dyes a screen can be made which appears red by lamplight and green by daylight, illustrating very well the peculiarity of the Alexandrite crystals.

Johns Hopkins University, Baltimore. R. W. WOOD.

Sun-pillar and Parhelion.

As the area over which such effects are visible is of some interest, it may be well to mention that a sun-pillar was visible in Dublin at 7 p.m. on Monday, April 28. It was preceded at 6 p.m. by an unusually fine parhelion display, a portion of which was hidden from my view by houses. Two concentric circles and an inverted arc touching the inner one were visible, with a mock sun at the left hand end of the horizontal diameter of the inner circle, and probably another, hidden from me, on the right. The wind all the previous day had been cold from the north-east, in a fairly clear air, and still blew from about north. The sky was full of streamers and wisps of cirrus cloud. Doubtless a far more complete account can be given by other observers. GRENVILLE A. J. COLE.

Royal College of Science, Dublin, April 30.

A Rare Wild Sheep.

SPORTSMEN and naturalists will be interested to learn that Mr. Talbot Clifton, who has recently been travelling in northern Siberia, has brought home from the valley of the Lena the skin and skull of a wild sheep of which no complete examples have hitherto been known in England. This sheep is the *Ovis borealis* of Severtzoff, a near ally of the bighorns of Kamchatka and Alaska. As it has no English name, it may well be known as Clifton's bighorn. The skin is being mounted by Rowland Ward, Ltd., and will before long be exhibited to the Zoological Society. R. LYDEKKER.

Beechen Hedges on Elevated Ground.

IN your issue of April 10, Mr. Wm. Gee, of Buxton, expresses his surprise that some beechen hedges and smaller trees in his neighbourhood have maintained their foliage through this winter, "contrary to the habit of deciduous trees."

I beg to state that in Denmark, where beeches abound, these trees always behave in the same manner as those in Buxton did this year. An underwood of young beeches, densely covered with dry, brown, rattling foliage, is quite a characteristic feature of Danish woodland scenery.

It would be most interesting to learn whether the beeches in England really used to throw off their leaves in autumn, and to ascertain the causes of such a different behaviour of the same species of tree in two countries of approximately the same climate. How this holding of the leaves could be a protective device to the individual young beech I cannot imagine; but to the whole underwood, or wood, this phenomenon might be protective, keeping out the cold winds of winter.

18 V. Boulevard, Copenhagen. JUL. WULFF.

IN reply to the interesting communication from Copenhagen anent the Buxton beeches, I would remind your correspondent that, as stated, the matured trees in the plantations hereabouts drop their leaves in the autumn as usual, the retention of them being observable only upon small young trees, and in the beechen hedges, and that this effect is not noticed, in this neighbourhood, for the first time.

It may give colour to the suggestion that this holding of the past season's leaves is an extra device under pressing circumstances to remember that the tissue of such accessory organs as scales, bracts and stipules is of feebly conducting material, and that these dry beech leaves, acting as such, would also enclose a film of air which would tend to give fuller protection from the frosts which this winter have been uncommonly severe, the local observatory (in connection with Westminster) registering down to 3° Fahr.

We have the highest authority for considering the beech as an unusually resourceful tree, as shown in its vernation, the growth of its bark and the care of its seeds; and it would not be surprising to hear of its making a special defence against a special attack, and being successful as a "survival of the fittest."

Barlbro' Cottage, Buxton, April 28. WM. GEE.

CHEMICAL INSTRUCTION AND CHEMICAL INDUSTRIES IN GERMANY.

NO more striking illustration of the position which Germany has won for herself in chemical technology, and of the industrial preeminence which she has thereby secured in one of the most highly developed branches of the chemical arts, could have been given than that afforded by Prof. Witt in the lecture theatre of the Royal Institution on Friday evening, March 21; and to the observant eye no object-lesson could be more significant or more forcible than that presented by the remarkable series of chemical products, the outcome of the work of German manufacturers, which Prof. Witt had gathered together to point the moral of his discourse.

In a few years we shall behold the extinction of one more agricultural industry, and the indigo plantations of India will have gone the way of the madder fields of Avignon. The death-knell of natural indigo has been sounded; the planter may struggle on for a while in a futile effort to withstand the inevitable; prejudice and trade customs may delay the fall of the fateful sword; but the machinations of the German chemist, backed by the German capitalist, have slowly but surely compassed his ruin, and it is but a question of time when it will be accomplished.

The conditions which have conduced to this result have been indicated, time and again, in these columns. But no more eloquent commentary on these causes could be adduced than is afforded by the report on chemical instruction and chemical industries in Germany recently made to the Foreign Office by Dr. Frederick Rose, His Majesty's Consul at Stuttgart, and which has recently been published.[1]

This report deals with the facilities, and expenditure, for chemical instruction at the two Prussian Technical High Schools at Berlin and Hanover, and at the University of Berlin, and is supplementary to a report on chemical instruction and chemical industries in Germany already made public by the Foreign Office.

The following brief analysis of this report will serve to show by what methods the State has deliberately

[1] Diplomatic and Consular Reports, No. 573, Miscellaneous Series.

paved the way for the result foreshadowed in at least one branch of chemistry in Prof. Witt's discourse.

Let us take the Berlin Technical High School first. In this school there are six fully qualified professors for the following branches of chemistry:—(1) Organic chemistry; (2) inorganic chemistry; (3) chemical technology; (4) metallurgy; (5) electrochemistry; (6) photochemistry.

In addition there are six lecturers for the following branches:—(1) Chemistry of foods, including analytical and bacteriological methods; (2) agricultural-chemical technology (sugar, beer, spirits, &c.); (3) vegetable and animal fats, oils, &c., investigation of mineral oils and naphtha products; (4) designing of chemical works and plant; (5) architectural chemical technology; (6) physical chemistry, thermochemistry, &c.

Finally, twelve *privat docenten*, or private lecturers, for the following branches:—(1) Electrolytic metallurgy; (2) chemistry of foods; (3) ceramics; (4) chemistry of the growth of plants; (5) investigation of oils, fats and naphtha; (6) technology of proteids and albuminoids; (7) repetition of organic chemistry; (8) chemistry of cements, mortar, plaster, &c.; (9) qualitative and quantitative analysis; (10) coal tar dyes; (11) terpenes and camphors; (12) modern synthetic drugs.

The following table gives the number of professors and students for a series of years from 1885–99:—

	1885.	1890.	1895.	1899.
Professors	4	5	5	6
Lecturers	3	2	6	8
Private lecturers	5	3	11	12
Assistants	7	13	13	15
Students	89	172	171	278

It will be seen that in 1899 there were no fewer than 41 professors, lecturers, private lecturers and assistants to 278 students, or about one instructor to seven instructed.

The laboratories for organic chemistry, photochemistry, metallurgy and chemical technology are contained in a building erected in 1884. The increase in the number of students has now rendered the erection of new buildings necessary; these will be begun this year, and will probably cost 27,500*l*. exclusive of the site, which is valued at 10,000*l*. For the same reason, a new building will shortly be erected for the electrochemical laboratory, which is at present located in the palatial building of the Technical High School.

The department for instruction in chemistry at the Hanover Technical High School differs from that of the Berlin Technical High School, inasmuch as the chemical-technical and electro-technical branches are combined in one department.

The principal chairs of chemistry are four in number:—(1) Inorganic chemistry; (2) organic chemistry; (3) chemical technology; (4) electrochemistry.

The following table gives the total number of professors, &c., and assistants and students for a series of years:—

	1885.	1890.	1895.	1899.
Professors	4	5	5	6
Lecturers	2	1	1	2
Private lecturers	—	1	4	4
Assistants	4	5	9	11
Students	64	81	192	285

In 1899 the proportion of instructors to instructed was 23 to 285, or about 1 to 12.

The department of chemistry at the Berlin University forms one of the subdivisions of the faculty of philosophy, and the professors of chemistry are members of the philosophical faculty.

The professorial staff includes:—(1) One professor of organic chemistry; (2) one professor of inorganic chemistry; (3) one professor of pharmaceutical chemistry; (4) one extraordinary professor of chemical technology; (5) one extraordinary professor from the Berlin Technical High School; (6) one extraordinary professor from the Veterinary High School; (7) one extraordinary professor from the Imperial Patent Office; (8) one extraordinary professor from the Royal Department for Testing Explosives; (9) three extraordinary professors who also form the managing board of the two principal chemical institutes (see under); (10) twelve private lecturers; (11) twenty assistants in the different laboratories for inorganic, organic, pharmaceutical and technological chemistry.

The chemical department of the Berlin University possesses the following subdivisions for chemical instruction:—(1) The First Institute of Chemistry, conducted by the professor with a managing board of two extraordinary professors and eleven assistants; (2) The Second Institute of Chemistry, with one managing extraordinary professor and three assistants; (3) The Chemical-Technological Institute, with one extraordinary professor and two assistants; (4) The Chemical-Pharmaceutical Institute, with one extraordinary professor and four assistants.

The report does not give the number of students of chemistry who have studied at Berlin during the past, as they are not inscribed specially as students of chemistry, but are entered as belonging to a subdivision of the philosophical faculty. It is not possible, therefore, to determine exactly what proportion of the total natural-science students were actually students of chemistry, although there is reason to assume that the proportion is large:—

	Students in the Philosophical Faculty.	Students in the subdivision of natural science.
1885	1955	813
1890	1761	515
1895	1551	512
1899	2162	784

It is stated that the decrease in the number of students for the years 1890 and 1895 was partially caused by the lack of sufficient and suitable accommodation in the chemical laboratories and lecture-rooms, a defect now remedied by the erection of the splendidly equipped building in the Sophien-Strasse.

The following table gives the annual expenditure for new apparatus, instruments, chemicals, repairs, &c., of the above-mentioned four chemical institutes at the Berlin University. The sums given do not include the salaries of teachers, assistants, or laboratory servants:—

	First Chemical Institute. £	Second Chemical Institute. £	Technological Institute £	Pharmaceutical Institute. £	Total. £
1885	645	724	476	275	2120
1890	719	564	398	275	1956
1895	794	564	398	275	2031
1899	1052	614	398	275	2339
1901	2792	614	398	275	4079

From the above table it is seen that the annual expenditure for the First Chemical Institute for instruments, apparatus, chemicals, &c., alone, *i.e.* apart from the salaries of the professors, lecturers, &c., has increased more than fourfold since 1885.

The First Chemical Institute was erected between 1860 and 1870 at the following cost:—

Building site	£13,500
,, expenses	27,505
Internal equipment	3,985
	44,990

During the last fifteen years, however, the great increase in the number of students of organic chemistry drawn to Berlin by the fame of Hofmann and Emil Fischer has rendered necessary the erection of a new building for the First Chemical Institute. This was built between 1897 and 1901 at a total expenditure of 70,000*l*.,

to which 7500*l*. was added for the purchase of instruments, apparatus, &c. The value of the building site was probably 30,000*l*. to 40,000*l*.

The Second Chemical Institute and the Technological Institute were both built after 1870, and have repeatedly received large sums for apparatus and instruments.

A new building is at present in course of erection for the Institute of Pharmaceutical Chemistry, estimated to cost 26,250*l*. without the value of the site, which may amount to 10,000*l*. The annual vote for instruments, &c., is to be raised from 225*l*. to 750*l*.

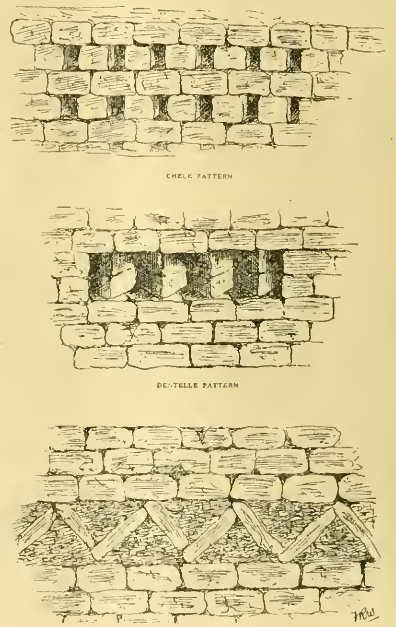
These figures, as Consul Rose states, are eloquent enough, and show clearly what facilities are provided in these great institutions for tuition in all branches of chemistry. "Finally they show—and this is, perhaps, the most significant indication of all—that the Prussian State, in spite of the expenditure already incurred, and the leading position attained by the chemical industries, is far from regarding the present admirable means of chemical instruction as adequate for future contingencies, but is at all times, after representations from the requisite industrial and educational quarters, prepared for further lavish outlay should future developments reveal this necessity." T. E. THORPE.

RHODESIA AND OPHIR.[1]

IN this handsome and copiously illustrated volume are embodied the results of six years' (1895–1900) systematic exploration amongst the numerous prehistoric remains of all kinds which are widely scattered over the whole region between the Zambesi and the Limpopo, and even range at some points into the conterminous districts of North Transvaal and Bechuanaland. During the operations, which were conducted under grants from the Chartered Company licensing these researches, the authors, with their indefatigable colleague, Mr. George Johnson, personally inspected nearly two hundred ruins, a list of which is here given and a great many of which are described in more or less detail. They further tell us that, so far from being completed, the work of exploration has scarcely been more than well begun, that their precursors and contemporaries—Bent, Mauch, Baines, Maund, Willoughby, Swan, Schlichter, White—have merely scratched the surface, and that of more than five hundred temples, citadels, enclosures, chains of forts, gold workings and terraced slopes reported from various districts and covering a total area of at least 115,000 square miles, not a tenth part has yet been thoroughly examined. This will be read with surprise by those archæologists who supposed that after Bent and Swan's classical descriptions of the "Great Zimbabwe" and a few neighbouring monuments, little more remained to be discovered. But the statement is supported by abundant first-hand evidence, and it is shown that Zimbabwe itself "is still practically unexplored," while elsewhere the original floors of the *earlier* structures still rest for the most part buried under ten or even fifteen feet of the accumulated débris of ages.

That there are earlier and later structures, bespeaking either a long continuous or an intermittent occupation of the land by foreign intruders, is placed beyond all doubt, and a comparative study of the various groups so far explored has enabled the authors tentatively to classify them in four categories, clearly indicating time sequences ranging from at least 1000 B.C., possibly even 2000 B.C., down to the advent of the Mohammedan Arabs and Portuguese. The buildings of the first period, of which the Great Zimbabwe is typical, are marked by great solidity and superior workmanship, with massive walls of dry masonry resting on the bed-rock, often 15 to 17 feet thick at base, batter-backed both inside and outside, with no false courses, but bonded throughout their entire width and diversely ornamented with dentelle, check, chevron and especially herring-bone patterns (Fig. 1). These are assigned with Bent, Schlichter and myself to the South Arabian Himyarites, and are compared—in their characteristic elliptical curves, the absence of mortar and other details—with the ruined temples and palaces of Marib (Maraiaba Bahramalakum), capital of the ancient Sabæan empire.

To the Phœnician successors of the Sabæans are assigned the less substantial and otherwise somewhat inferior structures of the second period, which are either superimposed upon, or else form extensions of, the earlier monuments, and also occur by themselves generally in



CHECK PATTERN

DENTELLE PATTERN

CHEVRON PATTERN

DECORATIVE PATTERNS

FIG. 1.

districts farther removed from the east coast. This is, of course, what we should expect to find on the assumption that the Himyarites were the first arrivals, and settled in the rich auriferous tracts (Manica, Sabi basin, Mashonaland) lying nearest to the seaboard. Yet remains of the first period are also met sporadically farther west in various parts of Matabililand, which may be explained either by assuming a very long pre-Phœnician Sabæan occupation or a joint Sabæo-Phœnician occupation probably in Solomonic times, when we know that peaceful relations prevailed between the Israelites, Hiram, King of Tyre, and Balkis, Queen of Sheba. It was then that the auriferous stream, which had already reached Palestine during the reign of David, rose to high-water level, and it is here suggested that

[1] "The Ancient Ruins of Rhodesia." By R. N. Hall and W. G. Neal with above seventy illustrations, maps and plans. Pp. xxvii + 396 (London Methuen and Co., 1902.) Price 21*s*. net.

the sources of that stream are to be sought in Rhodesia, where the ancient gold-workings are stated to have yielded a total output of at least 75,000,000*l*. Then it is asked, "Where else but Rhodesia did the ancient Sabæans obtain the vast supply of gold which they purveyed to Phœnicia, Egypt and the rest of the then known world? The only answer possible at present is: Rhodesia; and the later discoveries in Rhodesia only serve to strengthen and emphasise this answer." Hence the inference that Rhodesia was the Biblical Ophir, though the point is not regarded as settled. Indeed, in their preface, written after the appearance of my "Gold of Ophir," the authors seem inclined to adopt the modified view that Rhodesia was the source, and Ophir in South Arabia the importer and distributor, of these treasures throughout the ancient world. My conclusions bearing on this solution of the question are given in full, and seem to be tacitly accepted.

But the authors remind us more than once that their object has not been to advocate any particular theory, but "to allow facts to speak for themselves." Judged from this standpoint, the work must be pronounced an unqualified success. It would be impossible to improve upon the general plan, by which law and order is introduced into a chaos of small but indispensable details, brought together during six years of continuous exploration amid the ancient ruins south of the Zambesi. Students of Rhodesian antiquities will also feel grateful for the aid afforded by the accompanying large-scale map, which covers the whole ground and shows in red lettering the exact position of the five hundred ruined sites which have so far been either described or reported in every part of Rhodesia.

Limitation of space prevents more than the merest reference to many incidental matters, such as the structures now recognised as slave-pits, the extensive terraced slopes of the Inyanga and Mount Fura districts exactly resembling those of the Yemen uplands, the quartz crushers, the gold-smelting works, the numerous gold crucibles showing gold in the flux, and especially the massive gold objects—beads, bangles, plates, wire, pegs, nails, ferrules—which were so characteristic of the monuments of the first period, and of which more than 2000 ozs. have already been collected (Fig. 2). Some of the ornaments, obviously manufactured on the spot and displaying considerable artistic taste and technical skill, were found on the original cemented floors, while others were taken from the skeletons of men, women and children buried under the floors. "All the branches of the goldsmiths' art were practised by them, including gold wire drawing, beating gold into thin sheets, plating iron and bronze with gold, and burnishing" (p. 93). It is evident from such details as these, as well as from the slave-pits, the chains of forts stretching along the old highways seawards, and the terraced slopes erected with prodigious labour for agricultural purposes, that the country was not merely conquered, but settled, that it was a true colony in the modern sense of the term, and was held as such by the South Arabian Himyarites for many generations. But enough has perhaps been said to show the great value of a work which places the Ophir question on a new footing and sets history back some two millenniums in the austral world.

THE INSTITUTION OF ELECTRICAL ENGINEERS AND ELECTRICAL LEGISLATION.

Reference is made in our notes columns to the ceremony performed by Sir Frederick Bramwell in connection with the South Wales electrical power distribution scheme. The Bill for the promotion of this scheme was, it will be remembered, one of six before a Select Committee of Parliament presided over by Sir J. Kitson last year. These Bills gave rise to a paper read by Mr. W. L. Madgen before the Institution of Electrical Engineers on "The Electrical Power Bills of 1900: Before and After" (*Journal Inst. Elec. Engin.* vol. xxx. p. 475), in which the author dealt with the question of England's backwardness in the development of electrical engineering. The paper may be considered in some respects one of the most important communicated to the Institution of late years. It led to a prolonged discussion—the report of the proceedings occupies more than sixty pages of the Institution's *Journal*—in which, though various opinions were expressed as to the cause of our deficiency, the general conclusion seemed to be reached that the backwardness was due largely to the out-of-date and grandmotherly legislation which governed electrical undertakings. As a result, a powerful committee was appointed by the council of the Institution to report on the subject and advise the council whether they should take any action, and if so what action, to improve the position. The members of the committee were the following:—Profs. W. E. Ayrton, J. Perry and S. P. Thompson, Major P. Cardew, Lieut.-Colonel R. E.

Crompton, and Messrs. S. Z. de Ferranti, R. Hammond, H. Hirst, J. E. Kingsbury, W. L. Madgen, W. M. Mordey, R. P. Sellon, A. Siemens, C. P. Sparks, J. Swinburne and A. A. Campbell Swinton. This committee, after holding eleven meetings and collecting a quantity of evidence, has just published its report, which has been adopted by the council of the Institution. As the subject is one of vital importance, not only to the electrical profession, but to the whole nation, it will be of interest to consider this report in some detail.

By their first resolution the committee state that "the development of electrical science in the United Kingdom is in a backward condition as compared with other countries, in respect of practical application to the industrial and social requirements of the nation." As a case illustrating this contention, the American equipment of the Central London Railway will occur to everyone; the undisputed competition between Messrs. Ganz and Co. and the Westinghouse Company, two foreign firms, for the electrical equipment of the Metropolitan and District Railways affords a second illustration. The South Wales distribution scheme is a third case in point, for it will be seen from the note to which we have referred already that though the engines are to be of English make, the electrical generators are to be supplied from abroad.

The resolutions which follow attribute the backwardness largely to "the restrictive character of the legislation governing the initiation and development of electric power and traction undertakings, and the powers of obstruction granted to local authorities," and point out that "local boundaries have usually no reference whatever to the needs of the community in regard to electric supply and traction," and that the development of these undertakings offers the most favourable means of relieving congested centres. The economic importance of the question is thus clearly insisted upon by the committee. As regards the power of local authorities, it is recommended that the Electric Lighting Acts 1882-8 and the Tramways Act 1870 should be amended in so far as they enable local authorities to veto or delay electrical undertakings of proved public utility. A similar recommendation was made by a joint committee of the two Houses of Parliament in 1898, but nothing has been done so far to give effect thereto.

In addition, it is pointed out that the technical staffs of the Government departments are inadequate for present needs, and finally the committee recommends that a deputation from the Institution of Electrical Engineers should wait on the Prime Minister to urge the removal of the present disabilities and restrictions. It is to be hoped that this final resolution will take effect and will produce the desired result. It is not to be supposed that the legislative difficulty is the only one which has hampered electrical development in England, but it is unquestionably one of the greatest. As more than one speaker pointed out in the discussion on Mr. Madgen's paper, we have to cope with the superior organisation of foreign manufactories, due to the recognition of the high value of scientific training and the closer assimilation of theory and practice. In the industrial war which we have to carry on it is, as Prof. S. P. Thompson said, "brains really against which we have to fight." And we have to meet something more than this, namely, the experience which foreign manufacturers have gained in constructing electrical machinery, not for their own requirements merely, but for ours also. If we are to make up our leeway and be successful in this struggle, it is essential that we should not be hampered by out-of-date legislation. Reform may be necessary in other directions as well, but that does not lessen the need for reform in this direction. Anything that can be done to make our path more easy should be done without delay, lest we find, when it is accomplished, that we are too late. To do what is in their power for the furtherance of this object is the interest, not only of electrical engineers, but of all who do not desire to see our commercial supremacy pass to other countries.

DECORATIVE PLANTS FOR GARDENS.[1]

IN the second volume of the fifth series of the *Atti del Reale Istituto d'incoraggiamento di Napoli* (1901), Dr. Nicola Terraciano has an elaborate paper on the wild plants of Italy that are most suitable for decorative purposes in gardens. Such indications are greatly needed in many countries besides Italy. At this season of the year, if the botanist or the flower-lover pays a visit to a garden, or particularly to a flower-show, he will see hundreds of daffodils, for instance. If by chance he visits another locality he will still see hundreds of daffodils of the same kind. They are very beautiful, and to the student of evolution most interesting and most worthy of study. But after a time they get somewhat monotonous, and the visitor begins to long for a change. These daffodils of which we have been speaking may be referred to some two or three, or at most half a dozen, species only, but if we turn to the memoir before us we find some twenty species enumerated, and we wonder why more of them are not pressed into the service. Again, if we look to the "schedules" of the flower-shows at the Cape of Good Hope, or of any of our Australian colonies, we find slavish imitations of European procedures—chrysanthemums galore in their season, daffodils, roses and the like, just as in an English exhibition—but the representatives of the local floras are not represented. And yet the Cape flora and the West Australian flora are probably much richer in plants suitable for cultivation than those of any similar areas in the world. What a disappointment to the botanist to visit a flower-show in South Africa or Australia and find little or nothing but chrysanthemums when he is eager to see the beauties of the Cape Peninsula and of the Swan River.

Dr. Terraciano evidently holds the same views, for he puts before us a long list of the plants of Italy more or less suitable for garden decoration. He points out how great are the resources of the Italian peninsula, stretching as it does from Alpine almost to sub-tropical regions, with a long coast-line, with marshes, heaths, forests and endless diversity of soil, and situation clothed with a corresponding diversity of vegetation.

It is no wonder, then, that his list is a long one. There are fourteen species of tulips, for instance. Some of the plants might perhaps have been omitted, such as some of the eight species of Juncus. To the botanist pure and simple mere beauty is, of course, subordinated to other considerations. We remember a botanist's garden at Reigate many years since which was full of interesting things, but when the garden changed hands, the new proprietor is recorded to have said, when giving orders for their destruction, that he "must draw the line at docks"!

Dr. Terraciano indicates the soils most suitable for the cultivation of particular plants, and recommends for many of them a compost of peat, fragments of chestnut wood and leaf-mould.

Considering what a favourable nidus this would in our damp climate form for fungus spawn, we should hesitate to employ it on a large scale. Cultivation in sphagnum moss we first saw in Italy many years ago, and succeeded in growing sarracenias in it in a London suburb for a time.

[1] "Le piante della flora italiana più acconce all ornamento dei giardini."

NOTES.

THE following fifteen candidates have been selected by the council of the Royal Society to be recommended for election into the Society:—Mr. H. Brereton Baker, Prof. Henry T. Bovey, Prof. Rubert Boyce, Mr. John Brown, Mr. William Bate Hardy, Mr. Alfred Harker, Mr. Sidney S. Hough, Mr. Robert Kidston, Mr. Thomas Mather. Mr. John Henry Michell, Mr. Hugh Frank Newall, Prof. William M. Flinders Petrie, Mr. William Jackson Pope, Mr. Edward Saunders and Dr. Arthur Willey.

THE gold medal of the Linnean Society of London has this year been awarded to Prof. Rudolf Albert von Kölliker, of Würzburg, in recognition of his distinguished contributions to zoological science. The medal will be presented at the forthcoming anniversary meeting, which will be held at Burlington House on May 24.

WE are glad to learn that Prof. Rudolph Virchow has now recovered in what may be termed a highly satisfactory manner from the serious accident with which he met a few months ago. A few days ago he was able to leave Berlin for the country, where he will reside for some months to come, leave of absence having been granted him for the whole summer term. In the meantime, his duties of lecturing and examining will be undertaken by his three principal assistants.

AT the annual meeting of the Institution of Civil Engineers, held on April 29, Mr. J. C. Hawkshaw was elected president and Sir William White, K.C.B., Mr. F. W. Webb, Sir Guilford Molesworth, K.C.I.E., and Sir Alexander Binnie were elected vice-presidents of the Institution.

NEWS from the Swedish Antarctic expedition under Dr. Otto Nordenskjöld has been received by the *New York Herald*. The expedition has disembarked at Snow Hill, Louis Philippe Land, accompanied by the surgeon, Dr. Eklof, Lieutenant Sobral and two sailors. From Cape Horn Dr. Nordenskjöld tried to sail the *Antarctic* directly south, but too many icebergs were encountered and there was danger of the ship being imprisoned in the ice for a long time, so he decided to change his course. The expedition will remain at Snow Hill until next summer.

THE conversazione of the Institution of Electrical Engineers will be held in the Natural History Museum, South Kensington, on Tuesday, July 1. In view of the fact that the Tramways and Light Railways Congress will then be sitting, and many of the foreign delegates to the Congress are likely to attend the conversazione, and that the Incorporated Municipal Electrical Association will also open its convention in London on the following day, one of the large side galleries will be opened for the conversazione in addition to the central hall of the Museum.

THE seventh annual congress of the South-Eastern Union of Scientific Societies will be held at Canterbury on June 5–7. On Thursday, June 5, the president-elect, Dr. Jonathan Hutchinson, F.R.S., will deliver the annual address. The following papers will be read during the meeting:—"The Marine Aquarium, without Circulation or Change of Water," by Mr. Sibert Saunders; "Recent Researches on Mimicry in Insects," by Prof. E. B. Poulton, F.R.S.; "The Preservation of our Indigenous Flora, its Necessity, and the Means of Accomplishing it," by Prof. G. S. Boulger and Mr. E. A. Martin; "Borings in the Neighbourhood of Canterbury," by Mr. W. Whitaker, F.R.S.; "Mycorhiza, the Root Fungus," by Miss Annie Lorrain Smith. There will be an excursion to the South-Eastern Agricultural College, Wye, by the kind invitation of the principal, Prof. A. D. Hall, who will explain the valuable experimental work now being carried on in connection with the college.

THE Lawes Agricultural Trust Committee has appointed Mr. A. D. Hall, principal of the Agricultural College, Wye, to succeed the late Sir Henry Gilbert, F.R.S., as director of the Rothamsted Experimental Station. Principal Hall, who graduated at Oxford, and has since distinguished himself by his successful development of Wye College as a centre of agricultural education, will thus carry on the experiments which were jointly conducted by Sir John Bennet Lawes and Sir Henry Gilbert for nearly sixty years, and are now of worldwide fame. It is confidently expected that not only will the continuity of past work be maintained, but that agricultural science will be advanced in many new directions at this well-known centre of research.

THE *Times* announces the death, at Newcastle-on-Tyne, of Mr. John Glover, the inventor of the "Glover Tower," the introduction of which represented a great advance in the manufacture of sulphuric acid. Mr. Glover did not patent his invention, and never derived much pecuniary profit from it, but chemical manufacturers know the value of the boon he conferred on them, and the Society of Chemical Industry testified to the importance of his work by awarding him in 1896 its gold medal for conspicuous service to applied chemistry.

THE death of Prof. H. von Pechmann, in sad circumstances, on April 24, is a great loss to the science of chemistry in Germany. He had been ill for a long time past, suffering, it would appear, from an incurable nervous trouble and frequent attacks of mental depression. That he might be restored to health he was granted a long leave of absence, and on resuming his duties was seemingly better than he had been for some time. But soon after his return he again become depressed and, while in that state, put an end to his life by taking strong sulphuric acid in his laboratory. Prof. von Pechmann was only fifty-two years of age, having been born in 1850, and the University of Tübingen will feel his loss very keenly. Appointed to the chair of chemistry at the last-mentioned University in 1895 in succession to Prof. Lothar Meyer, his skill in teaching and his personal charm were such that the number of students under him increased very considerably and, as a consequence, the enlargement of his laboratory and lecture-theatre was regarded as necessary. The late professor was a native of Nüremberg, and descended from an old Bavarian family of great social influence.

THE council of the Institution of Civil Engineers has made the following awards for papers read and discussed before the Institution during the past session:—a Telford medal (in standard gold) to Mr. W. M. Mordey, and a George Stevenson medal (in standard gold) to Mr. B. M. Jenkin; a Watt medal (in standar gold) to Mr. J. A. F. Aspinall; and Telford premiums to Messrs. W. C. Copperthwaite, A. H. Haigh and J. Davis. The council has also awarded the Howard quinquennial prize of the Institution to Mr. R. A. Hadfield (of Sheffield) for his scientific work in investigating methods of treatment and new alloys of steel, and on account of the importance, in industry, of some of the new products introduced by him. The presentation of these awards, together with those for papers which have not been subject to discussion and will be announced later, will take place at the inaugural meeting of next session.

THE seventy-third anniversary meeting of the Zoological Society of London was held on April 29, the chair being taken by the Duke of Bedford, K.G., president of the Society. The report of the council announced that the Prince of Wales had become a vice-patron of the Society. In February last the council awarded the gold medal of the Society to Sir Harry H. Johnston, G.C.M.G., K.C.B. Sir Harry Johnston received the silver medal of the Society in 1894 in acknowledgment of his zoological investigations in

British Central Africa. Since that date he has not ceased his endeavours to promote the advance of zoological discovery in the several posts that he has occupied in various parts of Africa, and has especially distinguished himself by the discovery, on the confines of Uganda, of the wonderful new African animal the okapi. The silver medal of the Society was awarded to Mr. E. W. Harper, of Calcutta, who during the past two years has presented to the Society a large number of living Indian birds new to the collection. These medals will be delivered personally to the recipients at the general meeting on June 19. The total income of the Society during the past year was 29,350*l.*, and the ordinary expenditure amounted to 27,526*l.* The extraordinary expenditure paid in 1901, amounting to 4530*l.*, was devoted entirely to new buildings and works in the Gardens. The most important works carried on at the Gardens during the past year were the rebuilding of a portion of the green-houses and the new drains to the hippopotamus-house. Besides these works, a new ape-house for the better accommodation of the anthropoid apes was commenced last autumn, and a sum of 4000*l.* has already been expended upon it. The main feature of the new building is the entire separation of the part appropriated to the spectators from that in which the animals are lodged by a glass screen, so that the animals may be kept at a nearly uniform temperature. The number of visitors to the Society's Gardens in 1901 was 725,685, showing an increase of 28,507 as compared with the previous year and an increase of 61,130 above the average of the previous ten years. The number of animals living in the Gardens on December 31 last was 2922, of which 789 were mammals, 1575 birds and 558 reptiles and batrachians. Amongst the additions made during the past year, 10 mammals, 58 birds, 21 reptiles, 3 batrachians and 2 fishes were registered as new to the collection.

THE Electrochemical Society, which has just been founded in America, held its inaugural meeting at Philadelphia on April 3–5. The president is Prof. J. W. Richards, of Bethlehem, and the list of officers contains the names of most of the best-known American electrochemists. During the three days' session, twenty papers were read and discussed, and arrangements are being made, we understand, for the publication of the proceedings. The formation of this society is a sign of the importance which electrochemistry has attained in the United States. Tentative proposals have been made at various times for the formation of a similar society in this country, but it is doubtful whether there are a sufficient number of workers in this field to ensure its success. Perhaps the founding of the American society may stimulate English electrochemists to further effort in this direction. Some such organisation, in conjunction with the already existent electrochemical journal, might have the effect of bringing this country into line with Germany and America in this branch of electrical science.

WE noticed in these columns last year the starting of the first large power distribution scheme in England at Newcastle-on-Tyne. Last week, on April 29, Sir Frederick Bramwell laid the foundation-stone of the first generating station of the South Wales Electrical Power Distribution Company, thus inaugurating the second scheme in this country for the supply of electricity in bulk. The area that this company proposes to supply covers Glamorgan and a part of Monmouth, a total area of slightly more than 1000 square miles. The district is one eminently suited to the electrical distribution of power, as it includes collieries, steel-works, tin-plate and copper works and numerous other factories of different kinds. The generating station now being constructed is on the banks of the Taff, near Pontypridd, and it is expected that it will be completed in about eighteen months. The plant is to consist of five sets each having a capacity of 2250 kilowatts, making a total capacity of about 15,000 horse-power. Willans engines are to be used, driving three-phase alternators by Messrs. Ganz and Co., of Budapesth. These will generate current at 12,000 volts, which will be converted to low-tension continuous current to be supplied to consumers. The steam generating plant is to consist of twenty-four water-tube Niclausse boilers, which are being built by Messrs. Willans and Robinson at Chester. Three other generating stations will be erected later. It is estimated that the cost of generating power will be slightly over three farthings a unit, which will enable it to be sold cheaply whilst allowing a considerable margin for profit.

THE *Journal of Physical Chemistry* for January contains a paper by Prof. Kahlenberg on instantaneous chemical reactions and the electrolytic dissociation theory. A previous paper by the same author, in which he discussed the validity of the ionic theory of electrolysis, has been abstracted at considerable length in NATURE (vol. lxv. p. 305). In this second communication Prof. Kahlenberg attacks the theory that instantaneous chemical reactions are dependent upon ions; the question that the author sought to answer was whether these reactions, causing precipitation by double decomposition, can take place in non-conducting solutions. He finds that benzene solutions of chlorides, such as HCl, $SnCl_4$, PCl_3, $AsCl_3$ and $SiCl_3$, precipitate cupric chloride from a benzene solution of copper oleate. There is thus a reaction precisely analogous to the precipitation of silver chloride from silver nitrate solutions by means of a soluble chloride, although in this case both the reacting solutions are excellent insulators. The benzene copper and the benzene chloride solutions are no better conductors than benzene itself, nor is there any increase of conductivity at the moment of precipitation. Elaborate precautions were taken in all the experiments to exclude any trace of moisture. In addition, freezing- and boiling-point measurements were made on the copper oleate solution, as well as the conductivity tests, which showed that there was no electrolytic dissociation. The author concludes that, instantaneous reaction in insulating solutions having been thus demonstrated, similar reactions in aqueous solutions cannot be explained on the ionic hypothesis without further proof.

A COPY of the results of meteorological and magnetical observations at Stonyhurst College Observatory for 1901 has been received. The observations are very complete and are especially valuable from the fact that the means can be compared with those for the last fifty-four years. The total fall of rain in the year was close upon 39 inches, being 8 inches below the average. The shade temperature reached 89° on July 20, which is the highest recorded at Stonyhurst. The lowest shade temperature registered during this long series was 4°·6, on January 15, 1881. Drawings of the solar surface were made on 235 days. An appendix contains the results of meteorological observations taken at Malta, with means for the last eighteen years.

IN *Symons's Meteorological Magazine* for March, there are several communications from correspondents referring to the sun-pillar of March 6. It appeared to have been most strikingly visible in the south and south-west of England, and was also observed at some inland stations. An observer at Bridport states that at 6h. 10m. p.m. it shot upwards 10° perpendicularly above the horizon, and that its colour was yellow, tinted with orange. At 6h. 25m., when its altitude had lessened to 5°, it showed a remarkably intense rosy tint, and at 6h. 40m. scarcely a trace was left. The theory of the formation of the phenomenon is that the effect of a luminous shaft is given by reflection from the under surfaces of minute crystals of ice floating horizontally. The Rev. S. Barber points out that the result is precisely similar to the formation of a long shaft of light by the reflection of the moon on the rippled surface of the sea.

A HISTORICAL account of the discovery of voltaic electricity is contributed to Nos. 642 and 643 of *Prometheus* by Dr. F. Dannemann. It deals chiefly with the discoveries of Volta, Galvani, Oersted and Ampère, and the author considers that at the beginning of the twentieth year of the nineteenth century the chief fundamental facts concerning electricity had been made known with the exception of induction, which was left for the genius of Faraday to discover.

THE tendency of streams to diverge from a straight path and to assume a zigzag course forms the keynote to a paper by Mr. Lewis B. Haupt, on single curved *versus* double straight jetties, in the *Journal* of the Franklin Institute for April. Where a river assumes a sinusoidal form there is a constant tendency of the current to eat away the concave banks and to deposit silt on the convex ones, and the author considers that if this natural tendency is counteracted by confining the stream between two parallel straight jetties, much expense in dredging out the river bed will be incurred, whereas the construction of a single wall at the concave side of bends will enable Nature to do her own work by keeping the channel scoured at the side of the wall and forming a convex training bank at the other side. This method has been tried with success at Aransas Pass in Texas, and the author is of opinion that single concave reaction-jetties may economically be adapted to the opening of the delta mouths of silt-bearing streams.

A SHORT note in the *Journal* of the Royal Microscopical Society, on a paper by Mr. G. Marpmann on distinguishing between *Pleurosigma angulatum* and *P. balticum* under low powers, may well suggest an interesting field of observation in the diffraction colours of some of the more regularly marked diatoms, and the possibility of measuring the striations of the valves even by naked eye observations. By holding a slide thickly spread with any species of the genus Pleurosigma in full sunshine, it is easy to trace the diffraction colours through the various tints of the spectrum from violet to red and even to follow the second diffraction spectrum down to the green, and it is possible in this way to go further than Herr Marpmann would appear to have done so far as can be gathered from the note in question. If a slide of *Pleurosigma angulatum* or *quadratum* is held up in a bright light and a few of the much more coarsely marked *P. balticum* happen to be mixed with the other diatoms, the latter forms, by the different colours which they exhibit, are easily discernible to the naked eye. Two other papers allied to the above are also noted in the same journal, one by Mr. W. Balfour Stokes, who concludes that the minute perforations in *Pleurosigma formosum* are silted up with silica, and one by Mr. J. Rheinberg, who has succeeded, by placing a disc of a certain form above the objective of his microscope, in obtaining two images of the same diatom in complementary colours, one being a dioptric image and the other a diffraction image of the first order.

IN the course of excavating in the churchyard of St. George the Martyr, Southwark, in connection with the Long Lane street improvement, now being carried out by the London County Council, a very interesting discovery has been made. At a depth of about nine feet, some fragments of pottery and of ornamental terra-cotta work were discovered in a heap, as if at some time or other they had been thrown together promiscuously. The fragments were exhibited at a meeting of the Society of Antiquaries on April 17. Whilst the pottery is Roman, the terra-cotta work, the ornamentation of which is peculiar, dates from the time of Henry VIII., in whose reign the art was introduced into England. Stow says that "almost directly over against St. George's Church, was some time a large and most sumptuous house, built by Charles Brandon, late Duke of Suffolk, in the reign of Henry the Eighth, which was called Suffolk House." From Antony van den Wyngaerde's "View of London," circ. A.D. 1550, which contains the only representation of the house known, it appears that the mansion was built in the style of the early Renaissance, and it therefore seems very probable that the fragments in question had their origin in Suffolk House.

THE number of new species of American butterflies, mostly from Brazil, described by Mr. W. Schaus in No. 1262 of the *Proceedings* of the U.S. Museum (vol. xxiv.) may be taken as an indication of the large amount of work which remains to be done in South American entomology.

IN *Naturwissenschaftliche Wochenschrift* of April 27, Mr. C. Frings gives a *résumé* of the experiments made by Dr. Standfuss on hybridising Lepidoptera and the influence of temperature on the development of the pupa, to which allusion has been made in these columns on a previous occasion.

ONE of the most remarkable architectural structures in existence is the left-handed spiral staircase in the Chateau de Blois, Touraine, built during the sixteenth century from designs by Leonardo da Vinci. In a well-illustrated and thoughtful article published in the May number of the *Monthly Review*, Mr. Theodore Cook shows that the design of this staircase corresponds so exactly with the spirals on the common Mediterranean shell known as *Voluta vespertilio* as to leave little doubt that the artist had that shell before him as his model. The spiral on the central column of the core of the staircase corresponds exactly, for instance, with the spiral ridges on the columella of the volute, as seen in section. This of itself would be strong, although perhaps not absolutely convincing, evidence as to the origin of the design. But the staircase has also an exquisite outer balustrade, which shows a correspondence to the coils on the external spire of the shell as close as that which obtains between the interior of the staircase and the columella of the volute. Such a dual resemblance could scarcely be the result of coincidence, and the author seems therefore to be justified in the view he has taken. It is remarkable, however, that the spirals in the staircase run in the reverse direction to those in normal examples of the shell, that of the central shaft being left-handed instead of right-handed. The spirals are, in fact, those of a "reversed," or dextral, example of the shell, of which, perhaps, one in a million occurs in nature. That Leonardo da Vinci had such a reversed shell from which to copy is unlikely; but it is known that he was left-handed, and a left-handed man would naturally draw a reversed spiral. The author, we believe, has in hand a work on natural spirals in general.

THE April number of the *Record of Technical and Secondary Education* contains an important review, by Mr. W. M. Webb, of the means taken by the different County Councils in England for training teachers in the best methods of imparting "nature-knowledge" to their pupils. The prime object of such teaching is, of course, to make the pupils conversant with natural things by seeing and handling them in their own surroundings, and for this purpose field-excursions are absolutely necessary. Some educationists would indeed reserve the American term "nature-study" for observations of this class in which the relationships of animals and plants is not the main point of instruction. But such studies cannot be altogether separated from systematic biology, and the value of a thorough biological groundwork to the teacher is accordingly emphasised by the author. Prof. Bailey's leaflets, which have been adopted by the Board of Education as a basis of nature-study, are insufficient if systematic biology is to be really taught, and short courses on the best methods of teaching natural history

are therefore recommended, and have indeed been adopted by many of the County Councils. Mr. Webb's concluding summary and his observations on methods of training teachers, which are the outcome of many years' practical experience, may be commended to all interested in the subject. Much good is hoped to result from the Nature-Study Exhibition to be held in London in July. Educationists will then "be enabled to compare the results of the efforts to promote 'nature-study' which are now being made in many directions and under varied conditions, and in this way an opportunity will be afforded to shape and to consolidate opinion upon a branch of our educational economy which has escaped hitherto that concentrated attention so necessary for its development."

THE May number of the *Contemporary Review* contains two articles upon scientific subjects. Prof. W. Ramsay describes the present state of our knowledge of different forms of radioactivity and Mr. J. B. Carruthers deals with a subject of a more immediate economic interest, perhaps, viz. plant sanitation. After an explanatory introduction, necessary to introduce the general reader to the terms he afterwards employs, Prof. Ramsay gives a historical sketch of the work done in the direction of perfecting our knowledge of radiation, from the time of Davy down to the present day. He explains the general characteristics of ultra-violet, kathode and X-rays, and proceeds to treat in more detail the work of Poincaré, Henry, Curie, Debierne, Schmidt, Rutherford, Becquerel and others. In conclusion, Prof. Ramsay points the moral upon which NATURE has always insisted—"Whatever be the true explanations of these mysteries, it cannot be denied that they form the beginnings of what may, and almost certainly will, affect the material future of the human race. . . . It is true that investigators like Hertz, Lenard, Becquerel and the Curies do not make practical applications of their discoveries; but there is never any lack of men who discover their practical value and apply them to ends useful to mankind. All the more reason, therefore, that every encouragement should be given to the investigator, for it is to him that all our advances in physical and material well-being are ultimately due." Mr. Carruthers urges that if the same care were taken with plants as has been done to eliminate disease in men and animals, there would be many fewer plant troubles than the agriculturist has to contend with at the present time. He pleads for the introduction into this country of the means taken by the State in America, continental countries and some of our colonies, to discover and eradicate disease in plants.

WE have received the "Year Book of New South Wales," which contains much useful information intended mainly for those wishing to settle in the country. The history, physical features, soils, minerals, water-supplies, trade and commerce, crown lands and many other subjects are dealt with.

THE Yorkshire Geological and Polytechnic Society gives abundant evidence of its flourishing state in the last number of its *Proceedings* (new series, vol. xiv. part ii.), which contains no less than twelve papers and twenty-eight plates. We are glad to note a contribution from the pen of Prof. McKenny Hughes, on the physical geography of the district around Ingleborough. There are papers on glacial drift, on Carboniferous fishes and other subjects, and we may call special attention to a "first paper," by Mr. Robert Kidston, on the flora of the Carboniferous period, illustrated by thirteen excellent photographic plates of coal plants. There is also a memoir, accompanied by a portrait, of the late Mr. W. Percy Sladen.

IN Appendix iv. to the *Kew Bulletin* is given a list of the staffs at the Royal Botanic Gardens, Kew, and at such other botanical establishments at home, in India and the Colonies as are in correspondence with Kew.

WE have received the sixth set (reduced copies) of Blackie's South Kensington drawing cards, which portrays "plant forms" in the shape of leaves, fruits and flowers. Each full-sized set consists of twenty cards, measuring 28×20 inches. As the previous set deals with advanced ornament, the present series might with advantage have been more complex; also the comparison of the natural object and the same conventionally treated would have been instructive. As the reduced copies present the objects full size, it would be possible to combine the natural and the conventional on the same card without unduly diminishing the proportions.

THE bibliography of the literature of psychology and cognate subjects, issued annually under the title of the "Psychological Index" by the *Psychological Review*, is a very serviceable publication. The index for 1901, compiled by Prof. H. C. Warren, with the cooperation of Messrs. J. L. des Bancels, L. Hirschlaff, C. D. Isenberg and W. H. R. Rivers, has just been received, and it contains an orderly and comprehensive catalogue of French, German and English psychological publications issued during the year. There are nearly three thousand titles.

THE third edition of Prof. Erdmann's comprehensive "Lehrbuch der anorganischen Chemie" has been published by Messrs. F. Vieweg and Son, Brunswick. The original work was reviewed in these columns nearly three years ago (vol. lx. p. 289), and the new edition does not differ materially from it, though its value has been increased by revision and by the addition of about thirty new pages—bringing the total number up to 788 pages. The first part of the book is concerned with elementary chemical principles and methods, the second with non-metallic elements and the third with the metals. A long section at the end deals with the periodic law and some aspects of physical chemistry.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Miss Frost; a Long-eared Owl (*Asio otus*) European, presented by Miss Kate M. Hall; two Kestrels (*Tinnunculus alaudarius*) British, presented by Mr. Austin; a Black Francolin (*Francolinus vulgaris*) from the Coast of Syria, presented by Commodore Winsloe, H.M.S. *St. George*, a Short Python (*Python curtus*) from Borneo, presented by Mr. L. Wray; a Macaque Monkey (*Macacus cynomolgus*), a Bungoma River Turtle (*Emyda granosa*) from India, two Grey Monitors (*Varanus griseus*) from North Africa, a —— Anaconda (*Eunectes notoeus*), a Western Boa (*Boa occidentalis*) from Paraquay, ten Tessellated Snakes (*Tropidonotus tessellatus*), two Dahl's Snakes (*Zamenis dahli*), a Leopardine Snake (*Coluber leopardinus*), three Æsculapian Snakes (*Coluber longissimus*), a Lacertine Snake (*Coluber monspessulana*), a Dark-green Snake (*Zamenis gemonensis*) European, a Pel's Owl (*Scotopelia peli*) from Africa, a Many-zoned Hawk (*Melierax polyzonus*) from Morocco, deposited; a Brown Capuchin (*Cebus fatuellus*) from Guiana, ten Common Teal (*Querquedula crecca*) European, a Black-pointed Tequexin (*Tupinambis nigropunctatus*) from South America, purchased; a Barbary Wild Sheep (*Ovis tragelaphus*), two Mouflons (*Ovis musimon*), a Rufous-necked Wallaby (*Macropus ruficollis*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

CHANGES ON THE MOON'S SURFACE.—That the moon is a dead planet, devoid of water-vapour and air and consequently lacking any form of life, either of the animal or vegetable world, has long been the belief of astronomers. New light upon the history of our satellite is, however, beginning to dawn, and it seems that the imagination of Mr. H. G. Wells, which illustrated so vividly the seasonal changes on the moon's surface and the appearance of vegetation of rapid growth, is supported by actual

"results of observation," judging from an interesting article by Prof. William H. Pickering in the May number of the *Century Magazine*. Messrs. Pickering and Percival Lowell have during the last few years made numerous excellent observations on the planet Mars, and they have greatly increased our knowledge by accurately observing the surface markings and suggesting very plausible explanations of the phenomena observed. Such work was rendered possible by erecting an observatory in a locality where observing conditions were as near perfect as possible. Prof. Pickering has more recently turned his attention to an examination of the lunar surface, and the first results of this work have led him to some very definite and striking conclusions. The first of these is that there seems to be strong, if not fairly conclusive, evidence in favour of the idea that volcanic activity has not yet entirely ceased, and he quotes several instances in which small craters have disappeared while others have sprung up in different regions. The second, and perhaps more startling, announcement is that there is snow on the moon. He has observed that many craterlets are lined with a white substance which becomes very brilliant when illuminated by the sun, and a similar substance is found on the larger lunar craters and a few of the higher mountain peaks. The curious behaviour of these patches under different angles of illumination and their change of form have led him to suggest that an irregularly varying distribution of hoar frost may have something to do with the changes observed. The third remarkable deduction refers to the observations of "variable spots," which appear to be restricted between latitudes 55° north and 60° south; these spots are always associated with small craterlets or deep narrow clefts, and are often symmetrically arranged around the former. The alterations which these undergo have led him to seek the cause in the change in the nature of the reflecting surface, and the most simple explanation according to him is found in assuming that it is organic life resembling vegetation, but not necessarily identical with it. The new selenography consists, therefore, as Prof. Pickering remarks, "not in mere mapping of cold dead rocks and isolated craters, but in a study of the daily alterations that take place in small selected regions, where we find real, living changes, changes that cannot be explained by shifting shadows or varying librations of the lunar surface." Prof. Pickering illustrates his article with numerous excellent and instructive drawings and photographs of portions of the lunar surface, and these give the reader a good idea of the changes referred to in the text.

DUST-FALLS AND THEIR ORIGINS.[1]

FALLS of dust on a large scale are of rare occurrence, but one very often hears that in the south of Europe at such and such a place rain had fallen and had brought with it, and deposited on the ground, fine red or yellow dust. Thus on April 24, 1897, a south wind carried to southern Italy a great quantity of dust which was supposed to be of African origin.

Perhaps the most well-known instance of a fall on a large scale was that which occurred in May and August in the year 1883, when an enormous quantity of dust was hurled into the air during the Krakatoa eruption, and fell and was collected at various distances, the greatest being more than 1100 miles from the seat of the disturbance. The tremendous height to which the finer particles of dust were thrown, coupled with the movement of the air at this great distance from the earth's surface, were responsible for the magnificent coloured sunsets which were observed nearly all over the world. The volume[2] in which all these observations were collected is undoubtedly one of the most complete records of a "fall of dust" that has been published.

The large number of meteorological stations situated over the greater portion of the civilised world give us now greater chances for recording and tracing the paths of these falls of dust, whether they reach the earth's surface with or without the aid of rain. Fortunately, the tracks of the great dust storm of March 9–12 of last year and that of the minor storm of March 19–21 of the same year were restricted to such regions as these, passing over the coast of northern Africa and reaching Sicily, Italy, Austro-Hungary, Prussia, part of Russia, Denmark and even the British Isles.

In the volume before us, Profs. Hellmann and Meinardus have brought together all the information that could be collected by means of the distribution of circulars and communications with all meteorological stations, and discussed them in a very thorough and able manner, presenting us with a complete story, describing the locality from which the dust came, the means, direction and mode of transport, and finally the places over which it was deposited. The arrangement of the discussion is as follows:—The distribution of the dust over the land surface is first described, accompanied by the original accounts of the phenomenon as observed, a list of all places where the fall was recorded, and a map showing the general distribution. The meteorological conditions from March 9–12 are next dealt with, giving full details of the general atmospheric disturbances over the whole of Europe and North Africa, with numerous maps. The authors then give the individual reports on all the microscopic and chemical analyses of the dust from various localities, concluding with a brief account of the second fall of dust from March 19-21 and a general summary of the main results to which they have been led.

In these chapters the discussion of the facts collected has led the investigators to form a very concrete survey of the whole phenomenon, tracing the origin of the dust to dust-storms that occurred on March 8, 9 and 10 in the desert El Erg, situated in the southern part of Algeria, and which carried the dust and transported it northward.

This dust, as is here pointed out, began to fall at Algiers and Tunis in the dry state on the night of the 9th. The subsequent falls gradually took place northwards, first Sicily, then Italy, the Alps, Austro-Hungary, Germany, Denmark and European Russia, practically in the order named, coming in for their share. In Sicily and Italy the dust was noticed to have fallen even without the aid of rain, but in the other countries it was only detected during and after showers.

Not only did the dust-fall occur in these countries in the sequence mentioned, but the quantity that fell became gradually less the more north the places were situated, and the fineness of the dust, as shown by the analyses, increased at the same time. All these facts, as the authors indicate, are strong arguments in favour of the progress of the dust deposition from south to north, and the very minute and careful examination of the meteorological conditions stated here, showing a depression moving from south to north, endorse this point of view. There is little doubt, therefore, that the locality from which the dust originated was situated somewhere south of the northern shore of the African continent.

It is interesting to notice that the dust was not distributed homogeneously over the land areas, but in patches and streaks, some places, such as, for instance, the greater part of south Germany and Russian Poland, being entirely free from it, while others, such as the southern side of the eastern Alps and Holstein, being specially dense. The unequal distribution and different values for the rate of movement of the dust cloud seem to be adequately explained by the variable velocity of the air currents and the changing position of the barometric depression.

The investigation suggests that the dust was carried by a large mass of air which moved with great velocity from northern Africa to the north of Europe, and that this mass of air, cyclonic in nature, was fed on its western side by air currents from the north and on its eastern side by southerly currents; this accounts for the observed facts that the fall of dust was chiefly limited to the eastern portion of the depression.

As regards the total amount of dust that fell to the surface, rough estimates indicated that the weight of it would amount to about 1,800,000 tons, two-thirds of which were deposited to the south of the Alps.

The authors have shown that the most probable origin of the dust was the region to the south of Algeria, so that an examination of the dust that fell in Europe and elsewhere should consist of similar components as those that form the dust of this region. Nearly all the mineralogical, microscopic and chemical analyses point out that the dust is neither volcanic nor cosmic, but simply such as is found on the African continent. From exactly which part of the continent it came is evidently not certain, for some mineralogists suggested that the dust consisted

[1] "Der grosse Staubfall von 9 bis 12 Marz, 1901, in Nordafrica, Sud- und Mitteleuropa." Von G. Hellmann und W. Meinardus. *Abhandlungen des Königlich Preussischen Meteorologischen Institut*, Bd. ii. No. 1. (Berlin: A. Asher and Co., 1901.)

[2] "Report of the Krakatoa Committee of the Royal Society." (London: Trubner and Co., 1888.)

of the finest particles of Sahara sand, while others looked for its origin on laterite ground.

The value of the occurrences of falls of dust is of special moment meteorologically, because they afford us a means of obtaining further knowledge of the actual movements of the air currents in the higher reaches of our atmosphere which cannot be gained by any other such direct methods. Much valuable information was obtained of the movement of the air at great heights by the dust that was ejected during the eruption of Krakatoa, and as this volcano is situated near the equator, where the air currents have a great tendency to rise directly away from the earth's surface, the conditions were favourable for the dust reaching an extraordinary elevation.

Nevertheless, whether the falls owe their origin to dust storms in a desert or eruptions of large volcanoes, it is of great importance to meteorological science that they should be, not only accurately observed, but recorded and discussed. Fortunately, the fall in the present instance occurred where a great amount of useful data could be, and was, secured. In the handling of this material the authors are to be congratulated, for besides considerably increasing our knowledge of the way in which the dust is transported and enlightening us on other peculiarities of this interesting phenomenon, they have given us a volume which will serve as an excellent example for future recorders and observers. W. J. S. L.

BRITISH VERSUS AMERICAN LOCOMOTIVES.

A NOTEWORTHY Parlimentary paper has recently been issued containing correspondence respecting the comparative merits of British, Belgian and American built locomotives running on the Egyptian railways. The paper is full of interest to the locomotive engineer, bearing out as it does the unsatisfactory results obtained with American locomotives on British, Colonial and Indian railways when compared with the English design of engine, and, what is more, these unsatisfactory results are in all cases certified by the representative of the American firm of locomotive builders, as well as by an official appointed by the Egyptian railway authority, so there can be little doubt as to their accuracy.

Probably the most interesting report in the series is that by Mr. Trevithick, the locomotive engineer, who says:—

"The Mechanical Department of the Egyptian State Railways has recently made some interesting comparative trials between British and American locomotives of the same weight and power. These comparisons have been carried out under exceptionally favourable circumstances, inasmuch as the locomotives employed were typical of their respective countries in design and manufacture, and the trials were personally conducted, and the results conjointly signed, by a representative sent out by the American builders and a locomotive inspector of the Egyptian Railway Administration.

"The first set of trials, consisting of eight runs extending over 1034 miles, was between goods engines, and, in order to secure similar loads and to be able to gradually increase the weight of trains to the maximum that the respective engines could satisfactorily draw, the material transported consisted chiefly of coal.

"The total amount of coal consumed in the eight trips by the British engines was 22·84 tons, which works out at an average of 49 4lbs. per mile, whilst the American engines consumed 28·69 tons, an average of 62 lbs. per mile; in other words, for every 100 tons of coal consumed by the British engines the American engines burnt 125·4 tons, *i.e.* an excess of 25·4 per cent. This economy was effected by the British engines, although they drew a heavier average load, to the extent of 14·2 per cent. than the American, the average train taken by the British engines being 57 trucks, or 868 tons, as against 54 trucks, or 760 tons, the average train taken by the American. The maximum load taken by each make of engine was 61 trucks.

"These trials were followed by others between passenger types of engines, extending over 1345 miles; each make ran an equal number of trips with practically similar formation of trains, with the result that the British engines consumed a total of 18·47 tons of coal, or an average of 30·7 lbs. per mile, as against a total of 27·8 tons, or an average of 46·3 lbs. per mile, in the case of the American engines, which means that where the British engine consumed 100 tons, the American engine consumed 150 tons, or 50 per cent. more. Such a difference at 1*l.* 14*s.* 2*d.* per ton, the average price paid last year by the Railway Administration, represents an additional yearly cost per engine of 400*l.*; which is to say that these ten American engines would cost in coal in one year 4000*l.* more than the ten British engines, an amount almost sufficient to buy two new ones."

The above extract from Mr. Trevithick's report conclusively proves that the British type of locomotive is well able to hold its own in the three important matters of fuel and oil consumption, and cost of repairs. Much has been written lately on the standardisation of the locomotive, but in a progressive age this appears to be unnecessary, since the locomotive of yesterday must always be out of date. Much can, however, be done to assist locomotive builders in the way of standardisation of specifications and, more particularly, of the test requirements for the material.

It is absurd to think that consulting engineers cannot agree as to the best test requirements for, say, a crank axle or a steel boiler plate. With standard tests the locomotive builders could buy the material more cheaply, obtain quicker deliveries from the makers, and, probably, in their turn take less time to complete an order.

INTERFERENCE OF SOUND.[1]

FOR the purposes of laboratory or lecture experiments it is convenient to use a pitch so high that the sounds are nearly or altogether inaudible. The wave-lengths (1 to 3 cm.) are then tolerably small, and it becomes possible to imitate many interesting optical phenomena. The ear as the percipient is replaced by the high-pressure sensitive flame, introduced for this purpose by Tyndall, with the advantage that the effects are visible to a large audience.

As a source of sound a "bird-call" is usually convenient. A stream of air from a circular hole in a thin plate impinges centrically upon a similar hole in a parallel plate held at a little distance. Bird-calls are very easily made. The first plate, of 1 or 2 cm. in diameter, is cemented, or soldered, to the end of a short supply tube. The second plate may conveniently be made triangular, the turned-down corners being soldered to the first plate. For calls of medium pitch the holes may be made in tin plate. They may be as small as ½ mm. in diameter, and the distance between them as little as 1 mm. In any case the edges of the holes should be sharp and clean. There is no difficulty in obtaining wave-lengths (complete) as low as 1 cm., and with care wave-lengths of 0·6 cm. may be reached, corresponding to about 50,000 vibrations per second. In experimenting upon minimum wave-lengths, the distance between the call and the flame should not exceed 50 cm., and the flame should be adjusted to the verge of flaring ("Theory of Sound," 2nd ed., § 371). As most bird-calls are very dependent upon the precise pressure of the wind, a manometer in immediate connection is practically a necessity. The pressure, originally somewhat in excess, may be controlled by a screw pinch-cock operating on a rubber connecting tube.

In the experiments with conical horns or trumpets, it is important that no sound should issue except through these channels. The horns end in short lengths of brass tubing which fit tightly to a short length of tubing (A) soldered air-tight on the face of the front plate of the bird-call. So far there is no difficulty; but if the space between the plates be boxed in air-tight, the action of the call is interfered with. To meet this objection a tin-plate box is soldered air-tight to A, and is stuffed with cotton-wool kept in position by a *loosely* fitting lid at C. In this way very little sound can escape except through the tube A, and yet the call speaks much as usual. The manometer is connected at the side tube D. The wind is best supplied from a gas-holder.

With the steadily maintained sound of the bird-call there is no difficulty in measuring accurately the wave-lengths by the method of nodes and loops. A glass plate behind the flame, and mounted so as to be capable of sliding backwards and forwards, serves as reflecting wall. At the plate, and at any distance from it measured by an *even* number of quarter wave-lengths, there are nodes, where the flame does not respond. At intermediate distances, equal to *odd* multiples of the quarter wave-length, the effect upon the flame is a maximum. For the present purpose it is best to use nodes, so adjusting the sensitiveness of the flame that it only just recovers its height at the

[1] A Discourse delivered at the Royal Institution on Friday, January 17, by the Right Hon. Lord Rayleigh, F.R.S.

minimum. The movement of the screen required to pass over ten intervals from minimum to minimum may be measured, and gives at once the length of five complete progressive waves. For the bird-call used in the experiments of this lecture the wave-length is 2 cm. very nearly.

When the sound the wave-length of which is required is not maintained, the application of the method is, of course, more difficult. Nevertheless, results of considerable accuracy may be arrived at. A steel bar, about 22 cm. long, was so mounted as to be struck longitudinally every two or three seconds by a small hammer. Although in every position the flame shows some uneasiness at the stroke of the hammer, the distinction of loops and nodes is perfectly evident, and the measurement of wave-length can be effected with an accuracy of about 1 per cent. In the actual experiment the wave-length was nearly 3 cm.

The formation of stationary waves with nodes and loops by perpendicular reflection illustrates interference to a certain extent, but for the full development of the phenomenon the interfering sounds should be travelling in the same, or nearly the same, direction. The next example illustrates the theory of Huyghens' zones. Between the bird-call and the flame is placed a glass screen perforated with a circular hole. The size of the hole, the distances and the wave-length are so related to one another that the aperture just includes the first and second zones. The operation of the sounds passing these zones is antagonistic, and the flame shows no response until a part of the aperture is

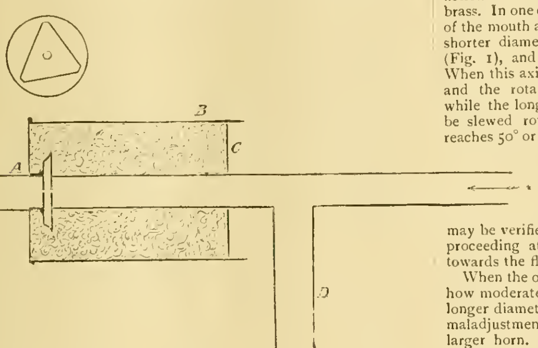

FIG. 1.

blocked off. The part blocked off may be either the central circle or the annular region defined as the second zone. In either case the flame flares, affording complete proof of interference of the parts of the sound transmitted by the aperture.

From a practical point of view, the passage of sound through apertures in walls is not of importance, but similar considerations apply to its issue from the mouths of horns, at least when the diameter of the mouth exceeds the half wave-length. The various parts of the sound are approximately in the same phase when they leave the aperture, but the effect upon an observer depends upon the phases of the sounds, not as they leave, but as they arrive. If one part has further to go than another, a phase discrepancy sets in. To a point in the axis of the horn, supposed to be directed horizontally, the distances to be travelled are the same, so that here the full effect is produced, but in oblique directions it is otherwise. When the obliquity is such that the nearest and furthest parts of the mouth differ in distance by rather more than one complete wave-length, the sound may disappear altogether through antagonism of equal and opposite effects. In practice the attainment of a complete silence would be interfered with by reflections, and in many cases by a composite character of sound, viz. by the simultaneous occurrence of more than one wave-length.

In the fog signals established on our coasts, the sound of powerful sirens issues from conical horns of circular cross-section. The influence of obliquity is usually very marked. When the sound is observed from a sufficient distance at sea, a deviation of even 20° from the axial line entails a considerable loss, to be further increased as the deviation rises to 40° or 60°. The difficulty thence arising is met, in the practice of the Trinity House, by the use of two distinct sirens and horns, the axes of the latter being inclined to one another at 120°. In this way an arc of 180° or more can be efficiently guarded, but a more equable distribution of the sound from a single horn remains a desideratum.

Guided by the considerations already explained, I ventured to recommend to the Trinity House the construction of horns of novel design, in which an attempt should be made to spread the sound out horizontally over the sea, and to prevent so much of it from being lost in an upward direction. The solution of the problem is found in a departure from the usual circular section and the substitution of an elliptical or elongated section, of which the short diameter, placed horizontally, does not exceed the half wave-length; while the long diameter, placed vertically, may amount to two wave-lengths or more. Obliquity in the *horizontal plane* does not now entail much difference of phase, but when the horizontal plane is departed from, such differences enter rapidly.

Horns upon this principle were constructed under the supervision of Mr. Matthews, and were tried in the course of the recent experiments off St. Catherine's. The results were considered promising, but want of time and the numerous obstacles which beset large-scale operations prevented an exhaustive examination.

On a laboratory scale there is no difficulty in illustrating the action of the elliptical horns. They may be made of thin sheet brass. In one case the total length is 20 cm., while the dimensions of the mouth are 5 cm. for the long diameter and 1½ cm. for the shorter diameter. The horn is fitted at its narrow end to A (Fig. 1), and can rotate about the common horizontal axis. When this axis is pointed directly at the flame, flaring ensues; and the rotation of the horn has no visible effect. If now, while the long diameter of the section remains vertical, the axis be slewed round in the horizontal plane until the obliquity reaches 50° or 60°, there is no important falling off in the response of the flame. But if at obliquities exceeding 20° or 30° the horn is rotated through a right angle, so as to bring the long diameter horizontal, the flame recovers as if the horn had ceased sounding. The fact that there is really no falling off may be verified with the aid of a reflector, by which the sound proceeding at first in the direction of the axis may be sent towards the flame.

When the obliquity is 60° or 70°, it is of great interest to observe how moderate a departure from the vertical adjustment of the longer diameter causes a cessation of effect. The influence of maladjustment is shown even more strikingly in the case of a larger horn. According to theory and observation, a serious falling off commences when the tilt is such that the difference of distances from the flame of the two extremities of the long diameter reaches the half wave-length—in this case 1 cm. It is thus abundantly proved that the sound issuing from the properly adjusted elliptical cone is confined to a comparatively narrow belt round the horizontal plane and that in this plane it covers efficiently an arc of 150° or 160°.

Another experiment, very easily executed with the apparatus already described, illustrates what are known in optics as Lloyd's bands. These bands are formed by the interference of the direct vibration with its very oblique reflection. If the bird-call is pointed toward the flame, flaring ensues. It is only necessary to hold a long board horizontally under the direct line to obtain a reflection. The effect depends upon the precise height at which the board is held. In some positions the direct and reflected vibrations cooperate at the flame, and the flaring is more pronounced than when the board is away. In other positions the waves are antagonistic, and the flame recovers as if no sound were reaching it at all. This experiment was made many years ago by Tyndall, who instituted it in order to explain the very puzzling phenomenon of the "silent area." In listening to fog signals from the sea it is not unfrequently found that the signal is lost at a distance of a mile or two and recovered at a greater distance in the same direction. During the recent experiments, the Committee of the Elder Brethren of the Trinity House had several opportunities of making this observation. That the surface of the sea must act in the manner supposed by Tyndall cannot be doubted, but there are two difficulties in the way of accepting the simple explanation as complete. According to it the interference should always be the same, which is

certainly not the case. Usually there is no silent area. Again, although according to the analogy of Lloyd's bands there might be a dark or silent place at a particular height above the water, say on the bridge of the *Irene*, the effect should be limited to the neighbourhood of the particular height. At a height above the water twice as great, or near the water level itself, the sound should be heard again. In the latter case there were some difficulties, arising from disturbing noises, in making a satisfactory trial; but as a matter of fact, neither by an observer up the mast nor by one near the water level was a sound lost on the bridge ever recovered.

The interference bands of Fresnel's experiment may be imitated by a bifurcation of the sound issuing from A (Fig. 1). For this purpose a sort of T-tube is fitted, the free ends being provided with small elliptical cones, similar to that already described, the axes of which are parallel and distant from one another by about 40 cm. The whole is constructed with regard to symmetry, so that sounds of equal intensity and of the same phase issue from the two cones the long diameters of which are vertical. If the distances of the burner from the mouths of the cones be precisely equal, the sounds arrive in the same phase and the flame flares vigorously. If, as by the hand held between, one of the sounds is cut off the flaring is reduced, showing that with this adjustment the two sounds are more powerful than one. By an almost imperceptible slewing round of the apparatus on its base-board, the adjustment above spoken of is upset and the flame is induced to recover its tall equilibrium condition. The sounds now reach the flame in opposition of phase and practically neutralise one another. That this is so is proved in a moment. If the hand be introduced between either orifice and the flame, flaring ensues, the sound not intercepted being free to produce its proper effect.

The analogy with Fresnel's bands would be most complete if we kept the sources of sound at rest and caused the burner to move transversely so as to occupy in succession places of maximum and minimum effect. It is more convenient with our apparatus and comes to the same thing, if we keep the burner fixed and move the sources transversely, sliding the base-board without rotation. In this way we may verify the formula, connecting the width of a band with the wave-length and the other geometrical data of the experiment.

The phase discrepancy necessary for interference may be introduced, without disturbing the equality of distances, by inserting in the path of one of the sounds a layer of gas having different acoustical properties from air. In the lecture carbonic acid was employed. This gas is about half as heavy again as air, so that the velocity of sound is less in the proportion of 1:1·25. If l be the thickness of the layer, the *retardation* is $\cdot 25 l$; and if this be equal to the half wave-length, the interposition of the layer causes a transition from complete agreement to complete opposition of phase. Two cells of tin plate were employed, fitted with tubes above and below, and closed with films of collodion. The films most convenient for this purpose are those formed upon water by the evaporation of a few drops of a solution of celluloid in pear-oil. These cells were placed one in the path of each sound, and the distances of the cones adjusted to maximum flaring. The insertion of carbonic acid into *one* cell quieted the flame, which flared again when the second cell was charged so as to restore symmetry. Similar effects were produced as the gas was allowed to run out at the lower tubes, so as to be replaced by air entering above.[1]

Many vibrating bodies give rise to sounds which are powerful in some directions but fail in others—a phenomenon that may be regarded as due to interference. The case of tuning forks (unmounted) is well known. In the lecture a small and thick wine-glass was vibrated, after the manner of a bell, with the aid of a violin bow. When any one of the four vibrating segments was presented to the flame, flaring ensued; but the response failed when the glass was so held at the same distance that its *axis* pointed to the flame. In this position the effects of adjacent segments neutralise one another and the aggregate is zero. Another example, which, strangely enough, does not appear to have been noticed, is afforded by the familiar open organ pipe. The vibrations issuing from the two ends are in the same phase as they start, so that if the two ends are equally distant from the percipient, the effects conspire. If, however, the pipe be pointed towards the percipient, there is a great falling off, inasmuch as the length of the pipe approximates to the half wave-length of the sound. The experiment may be made in the lecture-room with the sensitive flame and one of the highest pipes of an organ, but it succeeds better and is more striking when carried out in the open air with a pipe of lower pitch, simply listened to with the unaided ear of the observer. Within doors reflections complicate all experiments of this kind.

[1] In a still atmosphere the hot gases arising from lighted candles may be substituted for the layers of CO_2.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The 235th meeting of the Junior Scientific Club was held on May 2 in the physiological lecture room at the Museum. Two papers were read, "A New Type of Vertebrate Kidney," by Mr. E. S. Goodrich, Merton College, and "The Prussic Acid Problem," by Mr. J. M. Wadmore, Trinity College.

The ninth Robert Boyle lecture of the Junior Scientific Club will be delivered by Prof. T. Clifford Allbutt, F.R.S., in Balliol College Hall on Tuesday next, May 13. The subject will be "The Growth of the Experimental Method in Oxford."

THE honorary degree of LL.D. was conferred on Lord Kelvin on Monday by the University of Yale.

A MEETING will be held at the Mansion House to-morrow, May 9, at 3 p.m., with the Lord Mayor in the chair, in support of higher university education and research in London, with special reference to the fund being raised for the endowment of University College and its incorporation in the University of London. All who are interested in national progress and the advancement of knowledge are invited to take part in this movement for making up in some degree the gaps in our educational system, and in the endeavour to place at the disposal of the inhabitants of London facilities for mental training at any rate equal to those enjoyed by our continental neighbours. Among the speakers at the Mansion House meeting will be the Duke of Devonshire, Lord Brassey (chairman of the Appeal Committee), Lord Avebury, Mr. Ritchie, M.P., the Hon. Alban Gibbs, M.P., Sir Michael Foster, M.P., Principal Rücker, F.R.S., Mr. Lionel Phillips, and Mr. H. R. Beeton.

THE debate on the second reading of the Education Bill of the Government was opened in the House of Commons on Monday. Mr. Bryce gave reasons for believing that the Bill would not establish satisfactory local authorities, secure educational improvement, or effect a final settlement of the education question. Referring to secondary education, Mr. Bryce said that the Bill promises to do nothing for it, though secondary education is the most urgent of all our educational wants. "It does not direct any inquiry or any scheme to be made for the reorganisation of secondary education. It does not impose any duty upon the new authorities to provide secondary education, however great the local need may be. It is purely permissive. It does not contain any suggestion for dealing with endowments or for the reorganisation of schools It does not set apart the grant under the Act of 1890 as only applicable to secondary education. It gives a rating power up to 2*d*., with the possibility of increase by the consent of the Local Government Board. Secondary education ought to have had a Bill to itself, and it ought to have had a start of two or three years before primary education is thrown upon the same authority, if ever it is to be thrown upon it. Now, the probability is that secondary education will go to the wall." Sir John Gorst urged in reply that the Bill creates an authority, or it gives to the authority already existing for technical education full powers for secondary education, and so may be said to do something for secondary education. As to the inadequacy of the funds available under the Bill, it was held that the County Councils had enough to begin with, "and," added Sir John Gorst, "if this Bill is passed it will, at all events, make a beginning of secondary education, and when the authorities of counties and county boroughs see what sum of money is really required, I have no doubt the representations made by them to this House will be received with very fair consideration." The debate was continued on Tuesday, and among the points discussed were the comparative merits of School Boards and County Councils as local authorities for education, need for better training of teachers, the extension of the limit of a 2*d*. rate, and the need for generous grants from the Exchequer for secondary education.

THERE will be an exhibition of scientific apparatus at the conference of science teachers to be held at Festiniog on May 15 (see p. 599, April 24). Good apparatus is urgently required in many Welsh schools, and manufacturers ought to hasten to avail themselves of the opportunity which the conference affords of exhibiting instruments and materials essential to practical instruction in science. Mr. J. Griffith, County School, Festiniog, has entire charge of the exhibition arrangements, and would provide rooms and allocate space for the display of scientific apparatus.

THE Technical Education Board of the London County Council will shortly award five senior county scholarships. The scholarships are open to young men and young women who are resident within the administrative county of London whose parents are in receipt of an income not exceeding 400*l.* a year. They are tenable for three years at British or foreign Universities and technical colleges of University rank, and are of the value of 90*l.* a year. Candidates should as a rule be not more than twenty-two years of age, preference being given to those who are under nineteen years of age. In addition to the scholarships, the Board offers for competition a limited number of free places at the principal London colleges. Application forms can be obtained from the secretary of the Technical Education Board, and must be returned not later than Monday next, May 12.

A MEETING of the Association of Technical Institutions will be held between the second reading of the Government Education Bill and the Committee stage. At this meeting the council will recommend the Association to adopt the following resolutions in regard to the Bill:—(1) That this Association cordially approves the general principles upon which the Government Education Bill is based, and strongly urges His Majesty's Government to pass the Bill in the present session of Parliament. (2) That this Association is strongly of opinion that the new local authorities should be responsible for all grades of education in their districts, and that proper educational coordination would be seriously and unnecessarily hindered if this principle were not adopted; it therefore urges the Government to amend the Bill by deleting the clauses making it optional for the County and Borough Councils to undertake the supervision of elementary education. (3) That this Association regrets to note that the Bill makes optional the application to the purposes of higher education of the residue under the Local Taxation (Customs and Excise) Act, 1890, and it requests the Government to make such application compulsory. (4) That this Association regrets the exclusion of London from the Bill and trusts that the metropolis may receive attention early next year, and, while recognising that the case of London requires special treatment, is of opinion that it would be unwise to depart from the general principles of the present Bill in the case of London.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 12, 1901.—"On the Action of the Spurge (*Euphorbia hiberna*, L.) on Salmonoid Fishes." By H. M. Kyle, M.A., D.Sc., St. Andrews University. Communicased by Prof. McIntosh, F.R.S.

It has been known for some years that the Irish peasantry employed a simple method of procuring salmon and trout through the agency of the Spurge (*E. hiberna*, L.). The plant cut into small pieces and pounded with stones, or simply trampled upon at some convenient spot on a river, forms an emulsion in the water which, being swept downward into the pools, carries death to all fishes in its course. The fatality thus produced seems to have been enormous—80 to 100 salmon are reported to have been killed at one time, and again in the Bandon rivers 500 to 1000 fish of various descriptions are said to have been poisoned during one season. In the light of the experiments to be recorded presently, these statements do not seem exaggerated, for the Spurge-extract, even in small quantities, is almost as fatal to fishes as corrosive sublimate.

The fatal effect of the Spurge on fishes has been known in other countries besides Ireland, but to what ingredient or ingredients of the plant these effects are due seems never to have been investigated. The experiments described in the present paper throw considerable light upon the action of the Spurge, and open out to view some interesting problems.

Chemical analysis of the Spurge-extract shows that it contains tannic acid. Experiments on the circulation in the lung and mesentery of the frog reveal a close similarity between the action of the Spurge-extract and of tannic acid. In the case of trout the similarity extends to the non-recovery of the fish in fresh water, after they have come under the influence of either Spurge-extract or tannic acid. The power of the Spurge-extract to produce fatal effects persists for several days without diminution. Twenty per cent. of the fresh extract is fatal within five minutes, whilst 0·01 per cent. takes 4 to 6 hours, and seems to be the smallest percentage which has fatal results. In the case of fishes, death is considered to ensue from the inflammation of the gills and consequent stasis of the circulation, set up by the action of the tannic-acid component of the Spurge-extract. The fresh extract is calculated roughly to contain about 1 per cent. of tannic acid, but on this estimation the Spurge-extract is fatal within a shorter period than the corresponding quantity of tannic acid. Hence, the percentage of tannic acid has been under-estimated, or some other substance or substances in the extract also aid in producing fatal effects.

March 20.—"Persulphuric Acids." By Prof. Henry E. Armstrong, V.P.R.S., and T. Martin Lowry, D.Sc.

The "remarkable disappearance of oxygen" which Faraday, in 1834, observed to take place on electrolysing strong solutions of sulphuric acid was shown by Berthelot, in 1878, to be due mainly to peroxidation of the sulphuric acid. An anhydride, S_2O_7, was isolated, and he therefore concluded that the corresponding per*di*sulphuric acid, $H_2S_2O_8$, was formed when sulphuric acid was peroxidised either by anode oxidation or by interaction with hydrogen peroxide. The per*di*sulphates were isolated by Marshall, in 1891, by electrolysing solutions of acid sulphates, and have found a technical application in photography. This simple explanation of the peroxidation of sulphuric acid remained unchallenged until Caro found, in 1898, that when the per*di*sulphates are dissolved in sulphuric acid and the solution is again neutralised, a product is obtained which possesses the property of oxidising aniline to nitrosobenzene. None of the salts of Caro's modified persulphuric acid have yet been isolated, and only indirect methods are therefore available for determining its constitution.

Von Baeyer and Villiger have determined the ratio of sulphur to active oxygen in a solution containing the barium salt of Caro's acid, and found the ratio to be $SO_3 : O = 1 : 1$, the ratio for Marshall's salts being $SO_3 : O = 2 : 1$. They therefore assigned to Caro's acid the formula H_2SO_5 of a per*mono*sulphuric acid. If this acid be dibasic its salts must remain neutral when reduced, thus $CaSO_5 = CaSO_4 + O$, whereas any higher member of the series would liberate acid, thus $CaS_2O_8 + H_2O = CaSO_4 + H_2SO_4 + O$. Caro's salts are extremely unstable in presence of caustic alkalis, but neutral solutions can be prepared by neutralising with carbonates; when such solutions are heated they lose their active oxygen and liberate acid in the ratio $H_2SO_4 : O_2$. This result can only be reconciled with the formula of von Baeyer and Villiger by assuming per*mono*sulphuric acid to be monobasic, $NaHSO_5 = NaHSO_4 + O$; a more probable view is that Caro's acid is the *anhydro*-acid, $O\begin{cases}SO_2.O.OH\\SO_2.O.OH\end{cases}$, and that its salts are comparable with the *pyro*sulphates and the *di*chromates, $CaS_2O_9 + H_2O = CaSO_4 + H_2SO_4 + O_2$.

In concentrated solutions containing less than 50 per cent. of water, the peroxidation of sulphuric acid proceeds differently, the chief product being probably a per*tetra*sulphuric acid, $H_2S_4O_{14}$ (Lowry and West, Chem. Soc. *Trans.*, 1900, 950). This acid, the fourth member of the series $H_2O_2.nSO_3$, bears to pyrosulphuric acid the same relationship as that which per*di*sulphuric acid bears to sulphuric acid, $2H_2S_2O_7 - H_2 = H_2S_4O_{14}$, $2H_2SO_4 - H_2 = H_2S_2O_8$. On dilution and neutralisation it is hydrolysed to a salt of Caro's acid.

At the present time it is therefore necessary to postulate the existence of at least three persulphuric acids, in which the ratio $SO_3 : O$ is 1:1, 1 : 2 and 1 : 4 respectively. In spite of the stability of the perdisulphates, the least stable of these is per*di*sulphuric acid, for when liberated from its salts it rapidly passes in dilute solution to a per*mono*sulphuric acid (Caro's acid), whilst in presence of concentrated sulphuric acid it is converted mainly into per*tetra*sulphuric acid.

"On a Throw-testing Machine for Reversals of Mean Stress." By Osborne Reynolds, F.R.S., and J. H. Smith, M.Sc.

This research was undertaken at the suggestion of Prof.

Osborne Reynolds, who proposed an investigation of "repeated stress" on the following lines:—The stress should be direct tension, and compression of approximately equal amounts, such tension and compression being obtained by means of the inertia force of an oscillatory weight. The rapidity of repetitions should be much higher than in the experiments of Wöhler, Spangenberg, Bauschinger and Baker—in fact, ranging as high as 2000 reversals per minute.

The conclusions arrived at are:—

(1) The reversals for rupture with a given range of stress diminish as the periodicity of the reversals increases.

(2) The hard steels will not withstand a greater number of reversals of the same range of stress than the mild steels if the periodicity of the reversals is great.

Zoological Society, April 15.—Prof. G. B. Howes, F.R.S., vice-president, in the chair.—On behalf of Prof. F. Jeffrey Bell were exhibited two arms of an injured starfish of the genus Luidia from the west coast of Ireland, which had undergone repair at their ends. These regenerated parts were unlike the rest of the arm and had a striking, though not exact, resemblance to the free ends of the arms of an Astropecten.—Dr. Forsyth Major exhibited some selected specimens from a collection of fossil bones recently received by the Natural History Museum from Cyprus, where they had been discovered in caves by Miss Dorothy M. A. Bate. The remains proved to be those of a pigmy hippopotamus, about half the size of *Hippopotamus amphibius*, and could not be distinguished from Cuvier's "Petit *Hippopotame fossile*" (*H. minutus*, Blainv.), which was smaller than the so called "*H. minutus*" from Malta, and otherwise different. The fossils exhibited showed affinities on the one hand with the pigmy hippopotamus of Western Africa, "*Choeropsis liberiensis*," on the other with some remains from the Lower Pliocene of Casino (Italy); they were considered by the exhibitor as a further illustration of the assumption that many of the Pleistocene mammals of the Mediterranean islands were the little-modified survivors of Tertiary forms from the adjoining continents, from which the islands had been severed during the Tertiary period.—Mr. W. P. Pycraft read the fifth part of his "Contributions to the Osteology of Birds," which dealt with the Falconiformes.—Mr. F. E. Beddard, F.R.S., read a paper dealing with the sexual differences observed in the windpipe of the condor. It also treated of a rudimentary equivalent of the septal flap of the right auriculo-ventricular valve met with in the hearts of that bird and of a form of cuckoo (Scythrops).—A paper by Mr. Hesketh Prichard, on the larger mammals of Patagonia, contained field-notes on the huemul (*Xenelaphus bisulcus*), the puma (*Felis concolor*), Pearson's puma (*Felis concolor pearsoni*), the Patagonian cavy (*Cavia patagonica*), and the guanaco. The extraordinary tameness of the huemul was dwelt upon. The habits of the grey puma (*Felis concolor*) were described, a contrast being pointed out between their method of killing their prey and that of the jaguar (*Felis onca*). Pearson's puma, a new subspecies of puma, was alluded to as being much rarer than the grey puma, smaller, fiercer, and in colour reddish at the extremities. The fact of the distribution of the cavy (*Cavia patagonica*) being arbitrarily limited in the neighbourhood of the 45th parallel of latitude was commented upon as being strange, inasmuch as there was no change either in the vegetation or in the nature of the ground to account for it.—Mr. F. Pickard Cambridge read a paper on the spiders of the genus Latrodectus, which had a universally bad reputation of being extremely venomous in various parts of the world, although more exact evidence was required on this question. A list of the recognised species and subspecies was given.—A paper by Mr. Frank Finn contained some notes on the painted snipe (*Rostratula capensis*) and the pheasant-tailed jacana (*Hydrophasianus chirurgus*), of which birds he had recently presented some specimens to the Society's Gardens.—A paper by Mr. G. A. Boulenger, F.R.S., contained descriptions of eight new species of fishes from the Congo, forming part of a collection entrusted to him for study by the Director of the Royal Museum of Natural History in Brussels. The paper also contained a list of forty-one species of fishes from the Lindi River, Upper Congo, collected by M. Maurice Storms for the Brussels Museum.

Entomological Society, April 16.—The Rev. Canon Fowler, president, in the chair.—Mr. O. E. Jansen exhibited specimens of both sexes of *Ornithoptera victoriae* from Ysabel, Solomon Islands, recently taken by Mr. Albert Meek, and remarked on the variation in the colour and markings in the males.—Mr. H. W. Shepheard-Walwyn exhibited a series of *Euchelia jacobaeae* taken by him at Winchester in July 1889, showing considerable variations of size and colouring.—Mr. Willoughby Gardner exhibited *Coelioxys mandibularis*, Nyl., from the Cheshire coast, a species new to Britain; and *Osmia xanthomelana*, ♂ and ♀, and *Osmia parietina*, Curt., ♂ and ♀, from North Wales.—Mr. A. J. Chitty exhibited a specimen of *Aglais urticae* taken at sallow on March 28, having a large portion of the hind wings cut off so that when folded they were symmetrical in outline. From their appearance he concluded they had been bitten off by some animal, probably during hibernation.—Dr. T. A. Chapman called attention to the remarkable bilateral asymmetry in the male appendages of the Hemarid Sphinx, *Cephonodus hylas*, Linn. He said that bilateral asymmetry in insects was sufficiently rare to make it always notable. In the male apophyses of Lepidoptera he had only been able to find records in the case of the Hesperid genus Thanaos, to which Scudder and Burgess first called attention—though it seems highly probable that the facts can hardly have been unobserved in so common a species as *C. hylas*. He also exhibited specimens of the appendage removed from the insect, and of the several parts, as well as sketches of the clasps and tegumen.—Mr. C. P. Pickett exhibited many varieties and forms of *Hybernia leucophaearia* taken during March at Chingford, Highgate and Finchley. He also showed series of *Phigalia pedaria*, *Anisopteryx aescularia* and *Nyssia hispidaria* from the north metropolitan district.—Mr. H. J. Turner, on behalf of Mr. W. West, of Greenwich, exhibited specimens, ♂s and ♀s, of *Stictocoris flaveola*, Bohm., a species new to the British fauna, found amongst long grass in damp places at Lee, Kidbrook and Shooter's Hill, also several specimens of *Typhlocyba candidula*, Kir., a species first discovered by Mr. West at Lewisham and Blackheath on *Populus alba*.—Dr. D. Sharp communicated a paper by Miss Alice L. Embleton on the economic importance of the parasites of Coccidæ.—Colonel Charles Swinhoe read a paper entitled "Eastern and Australian Drepanulidæ, Epiplemidæ, Microniidæ and Geometridæ in the British Museum collection.—Mr. W. F. Kirby contributed a paper entitled "Additional Notes on Mr. Distant's Collection of African Locustidæ."

Royal Microscopical Society, April 16.—Dr. Hy. Woodward, F.R.S., president, in the chair.—A pocket microscope was presented on behalf of Mr. Jacob Pillischer. It was made by his uncle, Mr. M. Pillischer, and is described and figured in Dr. Golding Bird's work on "Urinary Deposits" (5th ed., 1857) The design is most ingenious. A small stage plate for carrying a 3" × 1" slide forms the base of the instrument; attached below to a jointed arm is a plane mirror and a diaphragm with suitable apertures. Above the plate and at one corner is a pillar carrying an arm, which reaches to the centre of the stage, for holding the lenses, which are Coddingtons of $\frac{1}{4}$, $\frac{1}{10}$, $\frac{1}{25}$ inch foci; the pillar contains a direct acting screw fine adjustment. The whole packs in a small case, which can be carried in the waistcoat pocket. With achromatic lenses it is a pattern which might have its uses at the present day.—Mr. C. Beck exhibited and described Standing's embedding microtome, an ingenious and simple hand microtome designed for cutting botanical sections, and extremely cheap. Mr. Beck also directed attention to some exceedingly fine rulings on glass, ruled by Mr. Grayson, of Melbourne. They had been brought from Australia by Mr. Wedeles, and were exhibited in the room. They were mounted in realgar, a medium having a refractive index of 2·5, which added considerably to the distinctness with which the lines could be seen. Three examples were exhibited, one being a micrometer divided into $\frac{1}{100}$ths and $\frac{1}{1000}$ths of an inch, and fourths, tenths and hundredths of a millimetre, another, a test plate of ten bands varying from 1000 to 10,000 lines to the inch, and another of twelve bands varying from 5000 to 60,000 lines to the inch. Mr. Wedeles stated that Mr. Grayson had ruled bands up to 120,000 lines to the inch.—Mr. J. C. Webb exhibited an old microscope by Pritchard the date of which he was unable to give, but thought it probably anterior to the advent of the engiscope which Pritchard brought out in 1832. The principal features of the instrument were a device for protecting the objective from injury when focussing—the first eyepiece was triple, it admitted plenty of light, and gave a good field with low powers. There was a fine adjustment to the nose-piece, and the body could be removed and the instrument used as a dissecting microscope.—Mr. Ersser ex-

hibited a reversible live box intended for use in observing large living objects, such as spiders while spinning their webs.—Messrs. Powell and Lealand exhibited a new $\frac{1}{12}$-inch semi-apochromatic homogeneous immersion objective of 1·4 N.A. It was made of glass which would stand any climate without deterioration, and the cost was exceedingly moderate.

Linnean Society, April 17.—Prof. S. H. Vines, F.R.S., president, in the chair.—Mr. A. C. Seward, F.R.S., read a paper by Miss S. O. Ford and himself on the anatomy of Todea, with notes on the affinity and geological history of the Osmundaceæ. The main points were:—(1) the investigation of the anatomical structure of Todea as represented by *T. barbara* and two of the filmy species, *T. superba* and *T. hymenophylloides*, with a view to a comparison with that of Osmunda; (2) a summary of the geological history of the Osmundaceæ and Osmundaceous characters; and (3) the question of the interpretation of the stelar structures of Osmunda and Todea.—On behalf of Mr. G. M. Thomson, of Dunedin, N Z., the Rev. T. R. R. Stebbing, F.R.S., read a paper on the New Zealand Phyllobranchiate Crustacea Macrura. This embodied a general revision of the group, with detailed descriptions and figures of several rare or imperfectly known species.

MANCHESTER.

Literary and Philosophical Society, April 29.—Mr. Charles Bailey, president, in the chair.—Mr. Frank F. Laidlaw made a communication on the peoples of Malacca. Special attention was directed to a number of savage nomadic communities, which inhabit the forest country of the interior for the most part. Owing to intermarriage between the various communities, as well as to the careless nomenclature employed in speaking of them, it is difficult to classify them in a satisfactory manner. In the northern half of the peninsula, however, these savages exhibit almost universally negrito characteristics, viz. curly (almost woolly) hair, very dark skins and moderately long skulls (mesaticephalic); the nose also is extremely wide and very flat. These negritos occur chiefly in Kedah, Kelantan and Perak. Considerable intermixture of negrito blood is also found in most of the southern wild tribes, whom many authorities believe to be derived from an admixture of Malay and negrito blood, but the evidence tends to show that in Perak, at least, there exists a second race quite distinct from negrito or Malay—a dolichocephalic, moderately fair-skinned race with wavy hair, and possibly allied to the Karens of Burmah. Lastly, the people of Johor, Selangor and Pahang are obviously of mongoloid stock. Like the other two groups, their stature is small (average height of a full-grown man 4ft. 6in., of a woman 4ft. 3½in.), but the hair is straight and the skull brachycephalic. It is not improbable that this latter group is largely descended from Malays who refused to adopt the creed of Islam; or they may perhaps more probably be derived from the widely spread pro-Malay race, of which the Malays themselves and the Javanese, &c, are specialised offshoots.

DUBLIN.

Royal Dublin Society, April 16.—Prof. D. J. Cunningham, F.R.S., in the chair.—Prof. John Joly, F.R.S., read a paper entitled "A Sedimentation Mystery."—Prof. G. A. J. Cole and Mr. T. Crook exhibited a large number of stones dredged by the Irish Fishery Survey from the Porcupine Bank and other places off western Ireland. They pointed out that the stones varied from one place to another so distinctly as to give a real clue to the submarine geology of the area. The basalt-plateau of the north was not here traceable, and the rocks in general represented submerged extensions of those known upon the western coast. The Porcupine Bank includes a large boss of olivine-gabbro like some of those associated with Carboniferous rocks in England. The description of the rocks is reserved for the Fishery Reports of the Department of Agriculture and Technical Instruction for Ireland.

Royal Irish Academy, April 28.—Prof. R. Atkinson, president, in the chair.—Prof. Chas. J. Joly read a paper on quaternion integrals depending on a single quaternion variable. The method employed is given in Hamilton's lectures, and the author indicated a simple step by means of which the fundamental theorems of Green and Stokes and their quaternion extensions may be deduced from Hamilton's results. The quaternion integrals must be either single, double, triple or quadruple; and in general the difference of two integrals of a given type taken between the same fixed limits but with different "modes of passage" is expressed as an integral involving one additional quaternion differential. Physical examples are given of the meaning of the different types of integrals, for example the conditions that the scalar double integral should be independent of the mode of passage are the well-known equations connecting the electric displacement and the magnetic force in a non-conducting dielectric.

PARIS.

Academy of Sciences, April 28.—M. Bouquet de la Grye in the chair.—The president announced to the Academy the death of M. Filhol.—Studies on batteries founded upon the reciprocal reaction of oxidising and reducing liquids. Common solvents. The action of acids on bases, by M. Berthelot.—On the treatment of malarial fevers by latent arsenic, by M. Armand Gautier. In a preliminary note published in February last, an account was given of the treatment of nine cases of malarial fever by injections of minute amounts of sodium methyl-arsenate. These results have now been extended, some twenty-three cases having been under treatment with entirely satisfactory results. All of these were severe cases which had proved refractory to the prolonged action of quinine, even in large doses. Out of ten cases of tertiary fever, four showed a slight relapse, the remaining six being completely cured by three successive injections of five to ten centigrams of the arsenical salt. In two cases of quaternary fever, the specific organism only disappeared after four or five successive injections of ·1 to ·2 gram. Detailed instructions are given for the mode of application of sodium methyl-arsenate in the various types of malarial fever.—The culture of the forage beet in the experimental field at Grignon in 1900 and 1901, by MM. P. Dehérain and C. Dupont. It has been previously shown that the beet giving the largest gross weight of roots per hectare is not necessarily the best for forage purposes. As the result of two years' experiments on the large scale, the variety known as *Géante demi sucrière rose* was found to be decidedly superior to the old forage beet. It was also found that the mode of arranging the plants was without effect on the yield provided that the number of roots per square metre did not exceed ten.—Geographical work round the central massif of Madagascar, by M. P. Colin. The present paper is confined to geodesic and astronomical results. The magnetic observations will be given in a future paper.—On the third voyage of the *Princess Alice II.*, by S. A. S. Prince Albert of Monaco. A *résumé* of the results in oceanography, geography, zoology, physiology and bacteriology.—Report presented by the commission charged with the scientific control of the geodesic operations at the Equator, by M. H. Poincaré.—Observations of the comet A (1902) made at the Observatory of Algiers with the 0·318 cm. equatorial, by MM. Rambaud and Sy.—On divergent series and differential equations, by M. Edmond Maillet.—The measurement of high temperatures and Stefan's law, by M. Féry. A cone of rays from the body the temperature of which is to be measured is concentrated by a fluor spar lens upon a delicate iron-constantin thermocouple. The temperatures indicated by this instrument were compared with those calculated by the law of Stefan; the error did not exceed 1 per cent.—A universal scale of periodic movements graduated in savarts and millisavarts, by M. A. Guillemin. The author proposes a new unit in acoustics to replace the octave and the comma. The use of the new unit, the millisavart, leads to a great simplification in numerical calculations.—On the graduation of thermoelectric couples, by M. Daniel Berthelot. The couples used were of platinum in contact with 10 per cent. platinum-iridium. The temperatures of five melting points and eight boiling points were determined by two couples independently, the maximum difference between the two being about 2° C. If e be the electromotive force of a thermocouple and t the centigrade temperature, log e is a linear function of log t for temperatures between 400° and 1100° C. This relation being assumed, it is only necessary to have two standard points to calibrate a couple, and for this purpose the melting points of zinc (419°) and gold (1064°) are recommended as the most suitable. With a good galvanometer there is no difficulty in obtaining a sensibility of 0°·1 C. in the neighbourhood of 1000° C.—On the indices of refraction of liquid mixtures, by M. Edm. van Aubel. According to a recent paper by M. Leduc, the refractive energy of a mixture of alcohol and water is the sum of its constituents if the contraction of volume which takes place on mixing is taken into account. Experimental results are now given for mixtures

of acetone and water, aniline and ethyl alcohol. In the case of the first mixture, the difference between the experimental figure and that calculated according to M. Leduc's hypothesis amounts as a maximum to four units in the fourth decimal place, in the second case the deviation amounts to double this amount. The conclusion is therefore drawn that the refractive energy, $n-1/d$, is not constant in liquid mixtures within the limits of experimental error.—Variations of the temperature of the open air in the zone comprised between a height of 8 and 13 kilometres, by M. L. Teisserenc de Bort. The results of the discussion of observations carried out in 236 captive balloon experiments. These results represent all seasons of the year and cover several years.—On the manufacture of certain metallic tools by the Egyptians, by M. Albert Colson. Analysis of an ancient Egyptian bronze tool.—The composition of the hydrate of chlorine, by M. de Forcrand. By the application of the principle described in previous papers, the conclusion is drawn that the composition of chlorine hydrate is $Cl_2.7H_2O$.—On some derivatives of oxyisopropylphosphinic acid, by M. C. Marie. The mode of preparation and properties of the sodium, lead, copper and silver salts.—On the transformation of proteids in plants during germination, by M. G. André.—Observations on orogenic poles, by M. Stanislas Meunier.—Glycosuria of muscular origin; the appearance of glycuronic compounds and glycose in the urine of animals submitted to a ligature or crushing of the muscles, by MM. Cadeac and Maignon.—Does lipase exist in normal serum? by MM. Doyon and A. Morel. Hanriot has supposed that there exists in normal serum of vertebrates a soluble ferment, lipase, which possesses the power of saponifying organic esters. None of the experiments here given support this view, and the existence in normal serum of a lipase acting upon olein cannot be demonstrated.—On acute polymicrobial osteomylitis, by M. Ragalski. In a case of osteomylitis of the clavicle, both the coli bacillus and staphylococcus were found to be present in the blood from the bone.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part 1 for 1902, contains the following memoirs communicated to the Society:—

January 11.—Emil Bose: on the nature of the electrical conduction in Nernst's electrolytic luminescent oxides. M. Abraham: the dynamics of the electron.

January 25.—Alfred Loewy: on reducible linear homogeneous differential equations.

February 8.—W. Voigt: contributions to the theory of pleochroic crystals. O. Wallach: researches from the University Chemical Laboratory (series x.)—(1) new syntheses in the terpene series; (2) on the separation of α- and β-methyladipinic acid; (3) on a series of new isomeric cyclic ketones of the formulæ $C_9H_{14}O$ and $C_9H_{16}O$; (4) on the formation of ϵ-betaines; (5) on phellandrene. C. Jacobi: contribution to the physiological action of the organic ammonium iodides and polyiodides.

THE REPRINT OF STOKES' PAPERS.

Mathematical and Physical Papers, vol. iii. By Sir G. G. Stokes. Pp. viii + 451. (Cambridge University Press, 1901.) Price 15*s*.

THE issue of the first volume of this work in the year 1880 was the beginning of the valuable series of reprints of mathematical and physical papers for which we are indebted to the Cambridge Press. It was felt at the time that no more auspicious beginning could have been made, and the publication was widely appreciated; but a gradual and increasing sense of disappointment supervened when, after the second volume, the continuation seemed to be suspended indefinitely. A third instalment has however now appeared, after the lapse of eighteen years, and although the regrets we have referred to cannot be altogether appeased, the contents of the volume will assure it of as hearty a welcome as was accorded to its predecessors.

There is little to be said now by way of comment on papers which have, most of them, long ranked as classics. The volume opens with the memoir on pendulums. The first, or theoretical, part of this contains the germ of almost all that has since been written mathematically on the subject of viscosity. In addition to the main topic, viz. the effect of viscosity of the air on the linear vibrations of a sphere or of a circular cylinder, we find the theory of the oscillating disc employed in Coulomb's experimental method (afterwards greatly improved by Maxwell), the calculation of the terminal velocity of a globule of water descending in air, and the general formula for the dissipation of energy in a viscous fluid, with (as an example) a discussion of the effect of viscosity on water waves. To appreciate fully the originality of this paper we must bear in mind that up to that time the subject had hardly advanced beyond the formulation of general equations; moreover, that a good deal of the analysis here applied to special problems was new, and devised expressly for the occasion; in particular, in the question of the oscillating cylinder an extremely difficult point in the theory of what are now known as Bessel's Functions was resolved with great success and for the first time. The second part of the paper consists of a comparison of the mathematical theory with Baily's experiments on pendulums, and includes the first numerical estimate of the coefficient of viscosity (μ) for air. The value thus obtained, although of the right order of magnitude, is considerably less than that now generally accepted; and, indeed, for the experimental determination of this constant the pendulum method would seem to be not specially appropriate. One source of uncertainty in the present determination is that μ was assumed, on the strength of an experiment of Sabine, to be proportional to the density, whereas Maxwell has since shown that for the same gas μ varies only with the temperature. The author tells us that one reason for the long delay in the appearance of this volume has been a design of revising the calculations from the point of view of Maxwell's result. This design is now abandoned, but an interesting note is inserted, explaining how it comes about that the erroneous assumption had so little effect on the *consistency* of the results. Another note, which also now appears for the first time, deals with the question as to the existence of *two* constants of viscosity for a gas. The usual formal theory, which makes no appeal to molecular hypothesis, leads to stress-formulæ of the types

$$p_{xx} = -p + \lambda\left(\frac{du}{dx} + \frac{dv}{dy} + \frac{dw}{dz}\right) + 2\mu\frac{du}{dx}, \text{ \&c.,}$$

$$p_{yz} = \mu\left(\frac{dw}{dy} + \frac{dv}{dz}\right), \text{ \&c.,}$$

involving the two constants λ, μ. The former of these is eliminated if we denote by p the *mean* normal pressure about the point (x, y, z), viz. we then have $\lambda = -\frac{2}{3}\mu$; but the question remains whether the p thus defined is identical with the "pressure" referred to in the statement of the Boyle-Mariotte law. The identity is assumed by most writers on the subject, and is supported by Maxwell's molecular theory; but it cannot be said that there is as yet any decisive experimental evidence on the point. There is a real physical question involved, viz. as to whether a *uniform* expansion or contraction of a gaseous mass does or does not involve dissipation of energy by viscosity.

The calculations of this memoir are, of course, based on the usual assumption that the terms of the second order in the velocities may be neglected. It has only lately been realised, thanks to a remark of Lord Rayleigh, to what an extremely narrow range of velocities we are sometimes confined by this limitation.

The next paper in the book discusses the effect of radiation of heat on the propagation of sound. It is shown that very slow and very rapid vibrations will alike be propagated without sensible thermal dissipation, the former with the "Newtonian" and the latter with the "Laplacian" velocity, whilst for intermediate frequencies there would be a real degradation. The investigation is reproduced, and extended to include thermal conduction, in Lord Rayleigh's "Theory of Sound."

The memoir on the most general form of the equations of conduction of heat in crystals is remarkable historically, and also on account of the attention paid to the possible occurrence of the "rotatory" coefficients. These are finally dismissed as improbable, but their analogues have in recent times been appealed to to explain certain phenomena of electric conduction under magnetic influence.

The remaining papers deal with optical questions. Those on the colours of thick plates and on the composition and resolution of independent streams of polarised light are important applications of established principles of physical optics; but the most notable in some respects is the great memoir on Fluorescence, with which the volume closes. This masterly analysis of the nature of the phenomenon was more fortunate than some of the author's previous work in the attention which it immediately attracted, not only at home, but abroad.[1] A

[1] Prof. Stokes' work on "Attractions and Hydrodynamics" was long neglected on the continent. I recall a sally of Maxwell's in one of his early lectures at Cambridge. Incidentally he remarked (with, I think, some investigation of Stokes in his mind), "But foreign men of science don't read the Cambridge *Transactions*"; then, guessing from the smiles of some of the audience that his words might be taken ambiguously, he added very emphatically, "It would be a good thing if they did!" One particular instance of erroneous ascription has a curious vitality. In a book dated 1900 we read, "Die Bewegung der Kugel in einer Flüssigkeit ist zuerst von Dirichlet behandelt," and in another dated last year, "Dies ist der von Dirichlet zuerst durchgeführte Fall." Yet both works are written by highly accomplished authors, with a sense of mathematical history.

D

most interesting note is now appended, in which the "Stokes theory of fluorescence," to which references have been made from time to time by Lord Kelvin and others, is expounded for the first time in the author's own words. Apart from the special application, the dynamical problem here employed by way of illustration is remarkable as the first example of the peculiarities of wave-propagation in a medium of "periodic" structure, a question which has been further elucidated by Lord Rayleigh.

The dates attached to the papers in this volume are all included in the interval from 1850 to 1852. The marvellous productiveness of the author, and the massive quality of the work which has left so little opening for subsequent correction or criticism, alike command our admiration. At the same time, we realise how great were the powers which from that period onwards were claimed in an increasing degree by the duties of the Lucasian professorship and by the secretaryship of the Royal Society. The generous and sympathetic manner in which these powers were placed at the service of younger workers now become a tradition of English science.

At the end of the preface we read, "There are other papers which still remain, and I hope, should life and health last, to put these together without delay." The "other papers" here so modestly referred to include such things as the "Communication of Vibrations" and the "Report on Physical Optics"! That the life and health may long continue, and that the promised continuation may speedily appear, will be the earnest desire of every reader of this volume. HORACE LAMB.

ANTHRACITE MINING IN PENNSYLVANIA.

The Anthracite Coal Industry. By Peter Roberts, Ph.D. Pp. xii + 261. (New York: the Macmillan Company; London: Macmillan and Co., Ltd., 1901.) Price 15*s.* net.

IT is not often that a great industry is discussed in so thorough and useful a manner as has been done by Dr. Roberts in this case. He has brought together information from a large number of sources, and he presents pictures from many points of view; his twelve chapters relate to geology, methods of mining, capitalisation, transport, management and inspection, workmen and wages, incidental profits, accidents, strikes, unionism, reworking old waste heaps and general reflections.

The days of the "mammoth vein," often exceeding 100 feet in thickness, are coming to an end, and we learn that much of the anthracite is obtained from seams only two to four feet thick. It is estimated that, allowing a yearly output of sixty million tons, the stock of anthracite will last for eighty years.

The actual cost of production is reckoned to be \$1·25 a ton, to which must be added royalties, insurance, office expenses and taxes amounting to about thirty-one cents, so that the total cost is about \$1·56.

Much has been said in this country about the danger of employing a few Poles in our collieries, on account of their imperfect knowledge of English. What should we think of a mining population talking twenty different languages, as happens in parts of the anthracite region? The majority of the alien colliers hail from Russia and Austro-Hungary. The author's ethnology is at fault, however, when he says that the Bohemians do not belong to the Sclav nations.

The chapter upon the incidental profits made by mining companies from running stores is by no means the least interesting; it seems that the truck system still flourishes in Pennsylvania, in spite of legislation against it, and that the workmen have a real grievance.

The accidents follow the usual lines; as in other districts, the proportion of fatalities due to falls of coal and rock approaches one-half of the total. The truth of the assertion that most of the accidents are due to carelessness on the part of the men themselves may be doubted, though the apologists of the owners and managers of mines on this side of the water are too ready to endorse this statement. Recent statistics show that, at all events in Germany, it is incorrect.

The author takes an unnecessarily pessimistic view concerning mining fatalities when he remarks that legislation is impotent to prevent them; the experience of European countries is totally opposed to this conclusion. However, a cursory glance at the statistics for Pennsylvania might lead an outsider to agree with Dr. Roberts, for he shows that after years of law-making the annual mortality-rate from accidents exceeds 3 per 1000. Unfortunately, he fails to make it clear whether this is the death-rate of the underground workers alone or that of all the persons employed both below and above ground. But in either case it is very high and very discreditable, and, what is worse, there are practically no signs of improvement during the last quarter of a century.

One cannot help suspecting that an inefficient method of enforcing the law may be at the root of the evil. Instead of being appointed for life, the inspectors hold office for five years only, and at a salary which in America may fail to secure thoroughly trustworthy and independent persons. It is not surprising, therefore, to find the suggestion that the inspectors are in the hands of the mine-owners. By a law which has come into force recently, the number of inspectors is to be increased, and they are to be elected by popular vote and for three years only. It will be interesting to watch how far this change will remedy the dangers of anthracite mining. Even if the next decade does show an improvement, it will not be necessary to ascribe it to the new inspectorial system. The author points out that a very powerful syndicate has lately acquired the control of four-fifths of the entire anthracite industry, and that with better administration, better discipline, improved methods of mining and increased use of machinery, the present dire waste of human life is likely to be diminished without any further legislative pressure.

While dealing specially with the anthracite industry, the author discusses various social and economic problems, and his book deserves the attention of mining men generally, whether employers or employed. It is a matter for regret that we have not similar works relating to each of our own coalfields, or at all events a general treatise dealing in a like manner with coal-mining in the British Isles.

ORGANOGRAPHY AND ITS RELATIONS TO BIOLOGICAL PROBLEMS.

Organographie der Pflanzen insbesondere der Archegoniaten und Samenpflanzen. Von Dr. K. Goebel, Professor a.d. Universität München. Zweiter theil, Heft 2 (schluss); mit 107 Abbild i. Text. (Jena: Gustav Fischer, 1901.)

THOSE who have read the parts of Prof. Goebel's "Organographie der Pflanzen" which have previously appeared will welcome the volume now before us, although perhaps with mixed feelings, in that it marks the conclusion of an interesting and suggestive work.

The present part is mainly devoted to a consideration of the shoot in relation to the reproductive functions, and the author has succeeded in presenting his subject in an admirable form. Many new observations will be noticed by the reader, and much besides of what is now familiar to botanists represents the outcome of original investigations conducted in the Munich laboratory. Some of the questions touched on are of a rather thorny nature, and Prof. Goebel is to be congratulated on the generally fair and judicious attitude which he preserves in regard to controversial issues thus incidentally raised.

As might have been anticipated, the account of the varied adaptations for the protection of sporangia, as well as for their dehiscence and the dispersal of the spores, is full of interest, and not less so is the treatment of the annulus regarded from a slightly different point of view. The diverse aspects of the same problem, when looked at from the standpoint of phylogeny or of utility, are well exemplified by the discussion based on the structure in question. The physiological stimulus which evokes what may turn out to be an *adapted* structure can only operate on and through the particular mechanism of the organism which can respond to it. And it is just this consideration which gives the clue that may enable us to understand the hereditary nature of a character which at first sight appears to be merely adaptive, and to see also how its importance as a criterion of toxonomic value is determined.

The vexed question as to the homologies of the structures met with in the female cone of the Coniferæ is briefly discussed, especially in relation to the abnormalities which have in the past played an important part in this connection, and the author well indicates the difficulties in correctly appreciating both the value and the cogency of this kind of evidence.

The chief deviations from the primitive character of a simple flower are also dealt with, and provide a good summary of our knowledge of the more salient facts. Some will probably hesitate to fully accept the case of *Pyrus malus* as representing a *real* transition from the perigynous to the epigynous form of gynæcium. The mature structure, as well as the developmental evidence, indicates (it may be argued) that this is a case of true perigyny, only somewhat obscured by the circumstance that the original and widening floor of the carpels has been tilted up instead of forming a horizontal expansion. It may be remarked in passing that the ovary of Primula is regarded as formed of five "paracarpic" carpels, and that the placenta is considered in this plant to represent a new formation, *i.e.* it consists of neither axis nor leaf as morphologically distinguishable. It is also remarked that the evidence which has been derived from a study of the distribution of the vascular strands is apt to prove ambiguous; the strands themselves are extremely variable and depend entirely on the physiological requirements of the ovules.

In dealing with the sporangia, the author makes the interesting suggestion that a feature of great diagnostic importance in separating angiosperms from gymnosperms may be found in the epidermal character of the cells which effect dehiscence in the microsporangia of the latter, whilst they are of hypodermal origin in the angiosperms.

Finally, the volume is brought to a close by an excellent account of many of the recent investigations on the biology of the embryo sac, in the elucidation of which Prof. Goebel's own pupils have taken an active part.

The book, as a whole, is characterised throughout by a freshness and vigour which is the outcome of a first-hand knowledge of the facts upon which it is based. Furthermore, whilst marking a definite advance as containing a large number of new facts, and especially as emphasising new points of view, it is a work which cannot fail to stimulate further research in many new directions.

J. B. FARMER.

OUR BOOK SHELF.

The Hurricanes of the Far East. By Prof. Dr. Paul Bergholz. English Translation, revised by Dr. Robert H. Scott, F.R.S. Pp. xvi + 271. (Bremen: Max Nössler; London: Norie.)

THIS book is a translation of Prof. Bergholz' "Orkane des fernen Ostens," and is intended as a seaman's guide to the typhoons and hurricanes of the China seas, of similar type to Eliot's "Handbook of Cyclonic Storms in the Bay of Bengal." It is, in fact, a digest of the results of the work of Vinez, Eliot, Doberck, Faura, and more especially of the recent papers of Algué, in much the same way as Eliot's "Handbook" is a digest of the elaborate "Cyclone Memoirs."

Prof. Bergholz divides his manual into four sections. The first deals with the general aspects of cyclonic phenomena—the structure of the cyclone itself, and the seasonal and geographical variations in its progressive movements. The typical cyclone is divided into four concentric zones, A, B, C, D; the zones A and B belong to the "outer whirl," C and D to the "inner vortex." Zone A extends from 120 to 500 miles from the centre, and is characterised by a slow fall of the barometer which does not seriously modify the diurnal curve of pressure. In zone B the centre is distant 60 to 120 miles, and the barometer shows a "distinct fall," which does not obliterate the daily curve, but displaces the hours of maximum and minimum. Zone C is a belt of "rapid fall," 10 to 60 miles from the centre; in it the diurnal curve disappears altogether. Zone D is a circle extending to 10 miles from the centre, within which the fall is "very rapid."

The classification of the cyclones runs along two lines, according to either the seasonal distribution or the course of the track followed by the system. The first becomes in effect a basis for subdivision of the main headings of the second, which are four in number:—(1) Cyclones of the Pacific, subdivided into cyclones of Japan and cyclones of the Magalhaes, (2) Cyclones of the China Sea exclusively, (3) Cyclones of the China Sea including the typhoons of Mindanao, Visayas and Luzon,

and (4) Cyclones of the Philippines. A further classification, useful for some purposes, is made according to the rate of motion of the cyclone in its path. In connection with this part of the subject, a valuable series of plates gives monthly averages of pressure and temperature, diurnal barometer curves, and a chart of cyclone tracks.

The second part of the book deals with the indications of the approach of cyclones. While the whole section is of immense practical value, two chapters, on the photography of clouds by the photo-theodolite and photographic means of distinguishing true from false cirrus, and on Fournier's rule and the use of Algué's barocyclonometer, are of special scientific interest. The third section describes special characteristic cyclones, with a chapter on anomalies, and the fourth treats of winter or land storms.

Bird Hunting on the White Nile. By H. F. Witherby. Pp. 117; illustrated. (London: *Knowledge* Office, 1902.)

Mr. Witherby may be congratulated, not only on having made a very successful bird-collecting trip to the White Nile, but also on having presented a narrative of his experiences to the public in an agreeable and well-written form. The several chapters of the book originally appeared as articles in *Knowledge*, from which they have been reprinted with the addition of two appendices and various slight amendments. The illustrations are also somewhat more numerous. The author tells us that he was unfortunate enough to lose all the photographs he took himself, owing to the intense heat and dryness; but he fortunately had with him a taxidermist who met with better luck in this respect, and it is to this gentleman that readers are indebted for the very interesting series of pictures with which the book is illustrated. Khartum is likely to become a popular winter resort, and tourists interested in the natural history and people will find Mr. Witherby's work an excellent and entertaining guide for the trip.

As is indicated by the title of his volume, the author had for his main object the birds of the country visited, and of these he was successful in obtaining a large number of species, of which a list is given in the appendix. Mammals, as is so generally the case, appeared to be excessively rare, and but few specimens were secured; these, however, proved to be of some interest, as they included a bat, a mouse and a hare which have been described as new. Mr. Witherby intersperses his ornithological observations with accounts of shooting and notes on the manners and customs of the natives in a way calculated to attract the attention of readers of all classes. Unfortunately, he was unable to obtain any evidence on the question whether the "crocodile-bird" really enters the mouth of the unwieldy reptile from which it takes its name. R. L.

An Introduction to Chemistry and Physics. By W. H. Perkin, jun., Ph.D., and Bevan Lean, D.Sc. Two volumes. Pp. xviii + 207 and xii + 216. (London: Macmillan and Co., Ltd., 1901.) Price 2*s.* each.

The special feature of these two small volumes is the treatment of the subject on historical lines, which is certainly a scientific method; for the young mind is asked to travel along the same track which the growth of the ideas has taken. This method lends itself to a more literary style than that of mathematical reasoning; and this, we think, is a gain, as the children in many science schools, where the time is chiefly taken up with science and mathematics, have little opportunity for such training.

Broadly, the first volume deals with physics and the second with chemistry. The metric system is explained at length, but we must confess that we should have preferred to see the gram described as a standard of mass and not of weight. It is certainly not true to say that a gram is *strictly* the weight of a cubic centimetre of water at 4° C., as the authors insist in the footnotes on pp. 18 and 20. It would not have been necessary to call attention to this had not great stress been laid on the fact that a metre is not exactly what it was originally meant to be.

In the experiments an accuracy of 1 per cent. is aimed at, yet in fixing the boiling point graduation on a thermometer, p. 43, the influence of the atmospheric pressure is not stated.

The present writer recently examined some 600 candidates in experimental science, and is able to trace many of their answers in these two books. As a rule these candidates seemed to follow the work well, but in some cases the principles of the experiments seemed beyond their power. Of all the quite elementary works of this class, perhaps these before us can be most strongly recommended to the consideration of the teachers in primary and secondary schools. S. S.

The Oil Chemists' Handbook. By Erastus Hopkins, A.M., B.Sc. Pp. viii + 72. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1900.) Price 3 dollars.

As stated in the introduction, the book has been written with the idea of supplying a want which has been felt for some practical working manual containing methods of examining oils and also data which will assist in the easy detection of adulteration and also give information as to what the adulterant is. The first chapter consists, in the main, of a series of tables of the general properties and uses of the oils and fats met with in commerce and of the solubility of oils, fats and waxes in various solvents. Following this are given the principles of the chief tests—the Maumené, Elaïdin, Warren's sulphur chloride test, &c.—and then, without an excessive amount of detail, the methods of analysis, in all cases references being given to the literature of the processes. The tables of chemical and physical constants which follow form an exceedingly useful collection, though the list might with advantage be a more complete one. In these tables the results of different observers are shown rather than mean figures, and the authors' names are given. In fact, this quotation of sources of information forms a distinct and important feature of the whole book.

Decidedly useful is a series of five tables arranging oils, fats and waxes according to (*a*) saponification value, (*b*) iodine value, (*c*) Reichert Meissl value, (*d*) Hehner value, and (*e*) acetyl value. The final chapters deal with, fatty acids, unsaponifiable matter (such as mineral oils, &c.), lactones, resin and glycerol.

Speaking generally, the book forms a valuable working companion for the oil chemist, without being a mere reference book.

Elements of Botany. By W. J. Browne, M.A. Lond., M.R.I.A. Fifth edition. Pp. viii + 272. (London: John Heywood, 1901.) Price 2*s.* 6*d.*

What is required of the elementary text-book nowadays is that it should furnish suitable directions and sufficient instruction to enable a student to collect, examine and work out the structure of plants for himself. The present work unfortunately follows the old style, being for a great part a mere catalogue of terms, or a series of descriptions, somewhat dry, relating to parts of the plant. In other respects, too, the book is quite unsuited to modern teaching; the appearance of Torula early in the book, presenting a huge nucleus, the idea that anatomical sections may be cut with a knife, the enumeration of the twenty-four classes of the Linnæan system, all suggest that the book has not yet been sufficiently modernised.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mont Pelée Eruption and Dust Falls.

FALLS of dust are caused in two ways; either the dust, as for instance Sahara sand, is transported by means of the lower air-currents over wide areas, or matter is ejected from volcanoes, thrown high up into the air and carried by the upper currents, falling eventually in places at great distances from the seat of disturbance. The eruption of Krakatão is a good example of the latter case, while the dust fall that occurred last year in March and was recorded in northern Africa, southern and northern Europe is a good representation of the former kind of dust fall.

The occurrence of such falls of dust is very interesting meteorologically, because they afford us means of increasing our knowledge of the actual movements of the air-currents, both low down and high up in our atmosphere. Falls of dust originating from volcanic eruptions are perhaps of greater interest, because the dust in such cases is thrown to very great heights, and we are able to deduce the directions of the currents at this elevation, there being no other method of doing so available.

To those interested in the movements of these upper currents, the recent disastrous eruption of Mont Pelée in Martinique may afford us some valuable information on this subject. From the accounts of the eruption already published, it is found that it occurred on May 8, and we gather from the information supplied by the British schooner *Ocean Traveller*, and printed in the *Times*, that when the ship was about a mile off St. Pierre, the volcano on Mont Pelée *exploded*. That the eruption was on a stupendous scale is undoubted from the numerous descriptions already made public, and the report from the British steamer *Esk*, which passed St. Pierre, that "she was covered with ashes although five miles distant from the land, and from on board nothing could be seen owing to the impenetrable darkness," gives some idea of the result of the disturbance. Later reports have indicated a further spreading of the dust, the island of Dominica recording a fall of sand on its southern boundary.

It is interesting for a moment to make a brief survey of the atmospheric circulation in the lower and upper reaches of the atmosphere in the region of the West Indies and to the north and south, and see whether we can trace out the probable path of the fine dust thrown into the air.

An examination of the fine pressure charts published in Bartholomew's "Atlas of Meteorology" tells us that during the month of May the West Indies lie between, but a little to the west of, two high-pressure regions, the more northern one being situated in the Atlantic Ocean and that to the south over the centre of South America, the intervening belt being one of low pressure. We also know that the sun has a declination of about 17° north at this time, and as the island of Martinique is situated in latitude about 15° north, the sun therefore passes daily near the zenith of that place, or, in other words, the sun is exerting its greatest heating power. In consequence of this fact, the low-pressure belt has a maximum in this region, and a low-pressure area means that the air is rising from the earth's surface into the higher regions. The two high-pressure areas already mentioned correspond to downcast shafts of air, *i.e.* air moving from higher to lower regions. With our present knowledge of atmospheric circulation it seems most probable that the heated air, rising into the upper reaches of the atmosphere from the low-pressure region (which includes the West Indies), bifurcates in a north-easterly direction in the northern hemisphere and in a south-easterly direction in the southern hemisphere. Since these currents of air must again reach the earth's surface, where they fall they will give indications of high pressure, *i.e.* indications of descent of air. As the two high-pressure areas already mentioned lie in the correct positions and directions in relation to the West Indies, it seems very probable that these are the downcast shafts corresponding to the upcast shaft or low-pressure area.

If the circulation above mentioned be correct, then, as the region of the volcanic eruption of Mont Pelée lies in this low-pressure area, some of the finest particles ejected to the upper reaches of the atmosphere might possibly be carried in these currents and begin to fall in these high-pressure areas. They may also, if the dust be thrown sufficiently high, reach that elevated current of air travelling from east to west and make a circuit of the earth, as was the case in the eruption of Krakatão.

The most favourable position in the northern hemisphere to observe this fall of dust, should there be such, would be probably in the middle of the Atlantic Ocean, and this could only be recorded by passing ships. Since, however, the descending air moves in a spiral manner and in the direction of the hands of a watch, some of this current reaches Britain as a south-west wind, and it will be interesting to see whether any fall be recorded. There seems little doubt, however, that, just as in the case of Krakatão, a great fall of dust fell to the westward of the volcano, so we shall probably soon hear in this case of such records from Mexico and Central America.

Further, the eruption of Krakatão was responsible for the magnificent coloured sunsets that were observed nearly all over the world, and as these were due to the fine dust particles ejected from the volcano—particles at very great altitudes—so it is quite probable that similar effects will ensue from the eruption of Mont Pelée.

It seems desirable, therefore, that information relating to the present eruption should be collected while facts are still in the memory of those who have observed them, and that a complete account be recorded similar to that published on the Krakatão eruption. It is satisfactory to learn that already expeditions are about to be sent from the United States of America to investigate the scene of the eruption.

WILLIAM J. S. LOCKYER.

Symbol for Partial Differentiation.

IN my college days we used the symbol $\left(\frac{du}{dx}\right)_y$ or $\left(\frac{du}{dx}\right)$ (if there was only one other independent variable y) as the differential coefficient when y was constant. I still keep to this symbol. Thus, if k is a certain kind of thermal capacity, $\left(\frac{dk}{dt}\right)_v$ or $\left(\frac{dk}{dt}\right)_p$ or $\left(\frac{dk}{dt}\right)_\phi$ are in my thermodynamic work perfectly definite. The mathematicians have introduced the convenient symbol for a partial differential coefficient $\frac{\partial u}{\partial x}$, and in much work there is no doubt about the meaning. But even in hydrodynamics there is trouble. In thermodynamics there is so much trouble with this symbol that I venture to ask for help.

The German translator of one of my books uses the same symbol $\frac{\partial k}{\partial t}$ for each of the above quite different things. Baynes in his thermodynamics does the same, and so do all other writers; it seems to me that everybody is doing this without thought. Are they writing for the average examination man who does not need to think, or for the real student? If the letter ∂ is to he retained, would it not be possible to use $\frac{\partial k}{\partial_v t}$ or $\frac{\partial k}{\partial_p t}$ or $\frac{\partial k}{\partial_\phi t}$ in the above three cases? I encourage my own students to use ∂, and I speak in the interest of such men. For myself it does not much matter, as I mean to continue using the symbolism of my youth.

May 6.

The Pines of Western Asia.

ON p. 15 of NATURE of May 1, it is stated that Herr Hugo Bretzl, in a thesis for his Doctorate at Strassburg, has shown that "the Greeks realised such facts as the absence of the pine in all the countries which intervene between Macedonia and India." That this statement is erroneous is proved by the following facts relating to the distribution of Macedonian and other species of *Pinus* in the countries alluded to. *P. Pinea*, Anatolia and Syria; *P. sylvestris*, Asia Minor, the Caucasus and Tauria; *P. halepensis*, Anatolia, Transcaucasia, Syria; *P. Brutia*, Asia Minor, the Lebanon, N. Persia; *P. Laricio*, Asia Minor. To these should be added various species of *Picea* and *Abies*, which the Greeks may have included under *Pinus*.

J. D. HOOKER.

THE pine referred to is *Pinus excelsa* Wall., which forms a feature of the Macedonian Mountains and also of the Himalayas,

but has not been found between Macedonia and Afghanistan. (Brandis, "Forest Flora of North-West and Central India," p. 511). Our thanks are due to Sir Joseph Hooker for pointing out that the statement as it stands suggests a wrong inference. THE WRITER OF THE NOTE.

The Kinetic Theory of Planetary Atmospheres.

THE much-debated question of the applicability of the kinetic theory to decide what gases can and what gases cannot exist in the atmospheres of planets is necessarily once more raised by a somewhat striking paper by M. E. Rogovsky in the *Astrophysical Journal* for November, 1901. In performing certain calculations contained in this paper which are embodied in Table III. (p. 254), the author bases his work on the assumption (p. 252) that ". . . the equation

$$W = \frac{\sqrt{(2ag)}}{10 \cdot 22}$$

where W is the most probable velocity of the molecules of a gas, gives the minimum most probable velocity in a gas which escapes from the surface of the given celestial body."

This is equivalent to assuming that a gas will escape if the velocity required by a molecule in order to overcome the planet's attraction and fly off to infinity (if it does not collide with other molecules) is not more than 10·22 times the most probable velocity.

Now if we calculate the probability of a molecule attaining a speed of 10 times the most probable velocity (to use round numbers), we find that the expression for this probability involves a factor of the form e^{-100}, that is about 10^{-43}, and this alone is sufficient to show that it is so rare for a molecule to attain a speed of 10 times the most probable velocity that such events cannot possibly have any appreciable effect on the planet's atmosphere.

Let us examine the matter a little closer, and in the first instance let us calculate the average proportion of molecules in any gas which have at any instant speeds of *not less* than 10 times the most probable velocity. The numerical result we obtain is

$$1 \text{ in } 2 \cdot 4 \cdot 10^{42}.$$

To interpret this result, let us suppose we are dealing with a gas one cubic centimetre of which contains 10^{21} molecules; this figure giving a rough estimate of the number of molecules in a cubic centimetre of air of ordinary temperatures and pressures. Then a volume of this gas equal to 2·4 times a cube the side of which is 100 *kilometres* will have to be taken in order that there may be an average of *one* molecule moving with a speed of 10 times the most probable velocity.

So far our calculations do not involve any considerations of *time*, although this must necessarily enter into the problem of escape of gas from a planet's atmosphere. Let us therefore now suppose the mass of gas under consideration to be bounded by a surface S, and let it further be supposed that every molecule which impinges on S with a speed greater than 10 times the most probable velocity escapes. Let the most probable velocity of the molecules be 1093 metres per second, the number assumed by M. Rogovsky for helium on p. 252 of his paper.

Then in order that the number of molecules removed in this way may be equal to the removal of a layer of the gas 1 millimetre thick all over the surface S, it will be necessary for about $2 \cdot 8 \times 10^{28}$ years to elapse.

Next suppose the surface S to be equal in area to the surface of our earth, namely a sphere 4×10^4 kilometres $= 4 \times 10^9$ centimetres in circumference. How many years would it take for a *cubic centimetre* of gas to escape? The answer comes out to be about $5 \cdot 371 \times 10^{10}$ years.

The only conclusion which can be drawn, not only from the present calculations, but also from others of a similar character[1] which have been made, is that a gas cannot escape from the atmosphere of a planet by the motion of its molecules among themselves without the aid of extraneous causes unless the most probable velocity of the molecules is considerably greater than one-tenth of the velocity required to overcome the planet's attraction.

[1] *Phil. Trans.* A. vol. cxcvi, pp. 1 24 (1901); also S. R. Cook, *Astrophysical Journal* January, 1900.

If helium is actually at the present time escaping from our atmosphere, its escape must be due to entirely different causes, and has to be investigated by entirely different methods from those contained in M. Rogovsky's paper. At all events, a most probable molecular velocity of not more than one-tenth, corresponding to a kinetic energy of not more than one-hundredth of that required to carry a molecule of the gas to infinity cannot have much influence in helping a gas to escape from a planet's atmosphere. And so soon as outside influences are invoked, the ratio of velocities which forms the basis of that portion of M. Rogovsky's work here considered ceases to be the determining factor of the problem. G. H. BRYAN.

Bangor.

On Prof. Arrhenius' Theory of Cometary Tails and Auroræ.

THE letter of Dr. J. Halm in your number of March 6 is based on two misunderstandings into which the writer could not have fallen if he had seen Arrhenius' original papers (*Physikalische Zeitschrift*, November 1900), or my description of them in the *Popular Science Monthly* (January 1902), instead of the friendly but erroneous notice of my paper in the *Observatory*.

(1) Dr. Halm quotes Prof. Schwarzschild to show that Arrhenius' theory "appears to be incompatible with any assumption which regards the cometary matter as being of a gaseous constituency."

Arrhenius never suggested that gaseous *molecules* could be propelled by the pressure of light. To quote my account of his theory:—"As the comet approaches the sun, the intense heat causes a violent eruption of hydrocarbon vapours on the side towards the sun. The hydrogen boils off, and the vapours condense into small drops of hydrocarbons with higher boiling points, or ultimately solid carbon is thrown out, finely divided as in an ordinary flame. The largest of these particles fall back to the comet, or if they are not condensed till at a great distance from it, they form tails turned towards the sun. The smaller are driven rapidly from the sun by the pressure of its light, with a speed depending on their size, and form the ordinary tails pointing away from it. That particles of different sizes should be formed from the same comet is natural, since the comet is likely to be formed of heterogeneous materials, and there must be great variety in the circumstances of condensation."

Dr. Halm does mention the idea of condensation into drops, and remarks, "Whether such an assumption can be justified appears to me very doubtful." This, of course, is merely his opinion, and receives no authority from the calculations of Prof. Schwarzschild. Indeed, in a recent letter to me, Arrhenius points out that these results fit the theory remarkably well. As Dr. Halm says, Prof. Schwarzschild reckons that "the corpuscles thrown off in the tails of comets should have diameters not smaller than $0 \cdot 07\mu$ and not exceeding $1 \cdot 5\mu$, supposing the specific gravity of the corpuscle to be that of water."

Now Arrhenius, in his original paper (November 1900), taking the specific gravity of the hydrocarbon drops to be 0·8, calculates the size of the particles required by his theory to account for the curvatures observed in the case of four different comets' tails, and finds them to be $0 \cdot 1\mu$, $0 \cdot 59\mu$, $0 \cdot 94\mu$, $1 \cdot 25\mu$. These values are distributed almost exactly over the interval within which light could exert a pressure greater than gravitation, according to the "exhaustive mathematical investigation" of Prof. Schwarzschild published a year later.

(2) Dr. Halm says:—"At any rate Prof. Schwarzschild's profound mathematical investigation makes it absolutely clear that the idea of minute electrically-charged corpuscles—about one-thousandth the size of a hydrogen atom (see *Observatory*)—being propelled by the sun's light towards the earth and causing the various phenomena of auroræ, Gegenschein, &c., receives no support from the mathematical point of view."

A reference to Arrhenius' paper and to my article will show that it is carefully explained in both that the charged (negative) particles are known to form excellent nuclei for condensation. It is the small drops so formed, and not the corpuscles, which, according to Arrhenius, are supposed to be driven off as far as the earth, and beyond it, giving rise to the auroræ, &c. As was seen above, Prof. Schwarzschild's results support such a view. JOHN COX.

McGill University, Montreal, March 19.

THE object of my letter to which Prof. Cox refers was to draw attention to certain statements made in recent accounts of Arrhenius' theory which were disproved by Prof. Schwarzschild's computations. I was fully aware at the time that Arrhenius himself had already arrived at the conclusinn that, to accord with his theory, the particles in the tails must be assumed to be liquid or solid. This was the necessary result of his computations, which had convinced him that the diameters of the particles must be between 0·1 and 6μ in order to satisfy Prof. Bredichin's values for the repulsive forces observed in comets. But how does Arrhenius' theory account for the presence of luminous vapours in the tail? In some recent comets the typical spectrum of the hydrocarbons was traced by Prof. Vogel to the farthest end of their tails. The emission of Comet 1881 iv. (Schaeberle) was almost entirely gaseous, and in Comet 1882 ii. even the sodium vapour was observed in the brighter parts of its luminous appendage. How are these vapours carried into the extreme parts of the tail, since the analysis of Prof. Schwarzschild shows that the pressure of light is far too insignificant to exert a repulsion upon the molecules of a gas or vapour?

Prof. Cox assumes the evaporation on the side facing the sun to be caused by the "intense heat" to which the comet is exposed on its approach towards our luminary. He thus attempts the revival of an hypothesis now abandoned by astrophysicists. Astronomers will find it somewhat difficult to comprehend how, for instance, the famous comet of 1811—one of the most remarkable phenomena of last century—which never approached the sun to the distance of our planet, could have received so intense a heat-supply that the "hydrogen of the hydrocarbons would boil off." But apart from this, the spectroscope has now clearly demonstrated the luminosity of the cometary substance to be due to disruptive electric discharges at a low temperature. The assumption of an "intense heat" causing the evaporation on the side towards the sun receives no support from the spectroscopic evidence. Moreover, the misty film surrounding the nucleus, the so-called atmosphere or coma, is certainly of extreme tenuity, and the mass of the comet cannot but be immeasurably small. Hence the hydrostatic pressure opposed to the outpouring vapours must be extremely insignificant. This necessarily involves low boiling points, so that condensation can only take place at very low temperatures. Hence we require at the same time an intense heat to boil off the hydrogen and an extremely low temperature to allow the condensation of the hydrocarbons into drops.

But even suppose that in spite of the intense heat and the low hydrostatic pressure condensation does take place on the side towards the sun, and that drops of hydrocarbons with less than the "critical" diameter are driven from the sun by the pressure of light. Can Prof. Cox demonstrate the possibility of these drops preserving their liquid state after having been launched into the vacuum of space? The permanent existence of drops of hydrocarbons in the tail is possible only under the condition that the space between the drops is saturated with hydrocarbon vapours. Here, then, we are again confronted with the question. How are these vapours carried into the tail, since the pressure of light has practically no repulsive power on the molecules of a gaseous substance? But if only drops, and no vapours, of hydrocarbon are repelled by the light-pressure, as Arrhenius assumes, what force prevents these drops from being instantaneously evaporated after once having departed from the outskirts of the comet's atmosphere and having started on their journey through the vacuum of space? Obviously the assumed drops ought to retain their initial bulk throughout the whole length of the tail, *i.e.* through a distance of hundreds of thousands of miles, all the time unsurrounded by any vapour, the tension of which might counteract the inherent tendency of the liquid to assume the gaseous state. Such an hypothesis is plainly impossible.

Prof. Cox mentions the possibility of solid particles being repelled by the light-pressure. He remarks that "ultimately solid carbon is thrown out, finely divided as in an ordinary flame." There is no objection to this assumption from the physical point of view. But is it sufficient to explain the characteristic forms of the tails and their classification into several distinct types? What reason can be adduced for particles of dust assuming only such dimensions as would lead in all the comets to only three or four particular repulsive forces out of an infinite number of possible varieties? Why have, for instance, in the forty comets investigated by Prof. Bredichin, the particles never assumed such dimensions as would correspond to types intermediate between Bredichin's first and second? The explanation of Prof. Arrhenius is very unsatisfactory. He says:—"Wenn nun zufolge gewisser Umstände einige Tropfengrössen die gewöhnlichsten sind, so können die wohlbekannten, relativ scharf begrenzten Schweife von verschiedener Krümmung entstehen." No attempt is made in his paper to show what these "certain circumstances" are, nor why they should lead to the same types of tails in comets with widely different conditions of evaporation and condensation. The results of Bredichin seem to me indeed to be irreconcilable with the present version of Arrhenius' theory, which in no way explains the remarkable selection of repulsive forces discovered by the distinguished Russian astronomer.

Another difficulty has been pointed out in my previous letter. It relates to the peculiar behaviour of the coma. In some comets a contraction of the coma has been observed on the approach of the comet towards perihelion, succeeded by an expansion after the perihelion had been passed. Thus the diameter of the coma of Encke's comet in 1838 was found by Valz to have shrunk from 280,000 miles at the solar distance 1·42 to only 3000 miles at perihelion. How is this phenomenon to be explained by the pressure of sunlight? In many instances (Comet 1862 ii., Respighi's and Henry's comet among others) the coma retained its globular form while the tail spread out and assumed enormous dimensions. But the spectroscope has now demonstrated that no difference exists between the coma and the tail with regard to the physical and chemical constitution of their materials. Hence the question remains still open why the pressure of light should repel the materials of the tail and yet at the same time leave the same materials in the coma entirely unaffected.

My objection to the theory of Arrhenius refers to those parts where he introduces Maxwell's pressure of light. I am perfectly at one with the Swedish physicist and with Prof. J. J. Thomson regarding the important part probably played by the negative electrons emitted by the celestial bodies. But I fail to understand why the pressure of light should be required to account for the discharge of negative electrons into space. Physicists tell us that a hot body like our sun is most probably the source for an energetic emission of free electric atoms. We are, moreover, acquainted with the fact that these free electrons possess enormous velocities. The measurements of Wiechert have shown the velocity to be between one-fifth and one-third of that of light. Now if the heat of the sun is capable of splitting off the negative electron from its atom, a great number of these free electric atoms must be flung into space simply on account of their enormous kinetic energy. For no form of matter leaving the upper strata of the solar atmosphere with a velocity exceeding 600 kilometres per second can possibly return to the sun. Why, then, should the free negative electron, with more than one hundred times this critical velocity, still require a force such as the pressure of light to be propelled into the universe? If we adopt Arrhenius' idea, according to which the free electrons first condense ordinary matter around themselves near the solar surface and are afterwards driven off by the pressure of light on this bulk of matter, we must find it difficult to understand how in some authenticated cases the action of a solar outburst on the magnetic instruments could have been instantaneous (see Young, "The Sun"). Granting the highest possible repulsive action of light-pressure on small particles, the solar electrons would require at least sixteen hours to reach the surface of our planet.

In my opinion, if we adopt the suggestion of Prof. J. J. Thomson that free negative electrons are probably emitted by the sun, a copious propagation of these infinitesimal corpuscles into space would be the obvious and necessary result of such an emission, even without the assumption of light-pressure.

The train of reasoning ensuing from this hypothesis would lead in a most natural way to Zöllner's celebrated theory of comets. By the abundant presence of electrons, space has then to be considered as a negatively charged electric field acting upon the *ionised* cometary matter. From this point of view, Zöllner's theory—according to Newcomb, the one "which on the whole most completely explains all the phenomena"—would no longer "lack the one thing needful to accept its reception," namely, "the evidence that the sun acts as an electrified body."

The main conclusion I have arrived at after a careful study of the theory of Arrhenius amounts to this: that by abandoning the assumption of the pressure of light and by assuming the propagation of free negative electrons from the sun into space

simply as a consequence of their great inherent velocity, the theory becomes admirably fitted to strengthen the views of Olbers, Zöllner and Bredichin with regard to the nature and the origin of the repulsive force acting upon the cometary matter. But the introduction of Maxwell's pressure of light gives rise to a number of difficulties which, as Prof. Arrhenius abundantly shows, can only be overcome by arbitrary and unwarranted assumptions.

I shall take an early opportunity of demonstrating the superiority of Zöllner's theory over the one which now claims to "sweep the astronomical horizon of so many mysteries."

Royal Observatory, Edinburgh. J. HALM.

Stopping down the Lens of the Human Eye.

MAY I be permitted to direct Mr. Wm. Andrews' attention to the fact that his experiment in "stopping down" the lens of the eye involves exactly the same principle as "orthoptics," of which every rifle-shot will have had experience.

The "orthoptic" consists of a round hole in a black disc, which replaces the lens of a pair of spectacles. The hole is generally adjustable in size, to suit varying conditions of light. The purpose of the orthoptic is to increase the *depth* of focus, enabling both back and fore sights and the target to be in sharp focus together. Persons with naturally large pupils will, as a rule, notice the effect more strongly. H. BLISS.

May 9.

IT may interest your readers to know that the principle referred to, under the above heading, in your issue of May 8 was adopted, a great many years ago, by the late Lord Sherbrooke, whose sight I believe was very defective. I remember seeing, about the middle of the seventies of the last century, at an exhibition of physical apparatus at South Kensington, a pair of spectacles which were said to have been invented by him for his own use. They consisted of two convex metal cups, closely resembling in shape and size the bowl of an ordinary tea-spoon. In the centre of each cup was a small pin-hole, which was the only aperture through which light could enter; and the two cups were fastened together by an elastic string, evidently intended to go over the head. The invention impressed me at the time as a remarkable example of scientific skill combined with great simplicity of contrivance.

GERALD MOLLOY.

The Evolution of Snails in the Bahama Islands.

IT seems desirable to call the attention of evolutionists to Dr. H. A. Pilsbry's monograph of the genus Cerion (or Strophia), just published in the "Manual of Conchology." The facts presented are most of them not new, but all that is known is set forth in great detail, with an abundance of excellent figures. Cerion is a genus of rather large cylindrical land-shells, for the most part inhabiting the Bahamas and Cuba. It has split up into innumerable local species and races, 134 of which are recognised as sufficiently distinct to bear names. Not only do even the smallest islands or "keys" produce distinct species, but frequently one small island will have two or more different forms inhabiting different parts, and sometimes a distinct race will occupy a very small area, surrounded on all sides by another type. The problem of the differentiation of the Achatinellidæ in the Hawaiian Islands is complicated by the complexity of their environment; but here in the Bahamas we have differentiation just as marked, with an environment—small sandy islands with palms and low bushes—as simple as we are likely to find anywhere. It would therefore seem that an excellent opportunity lies before some student of evolution to investigate exhaustively the local species and races of these Bahama snails, and determine what causes have brought about the known results. Colonies could be taken to new localities, and watched from year to year to see whether they became modified. The food and moisture conditions might be altered, and the results observed. The exact conditions surrounding each distinct form might be studied and described. Thus it might be determined whether the differentiation was the result of natural selection or has taken place independently of it. Such an investigation would be delightful work for some enthusiastic naturalist, especially with such an excellent guide in hand as Dr. Pilsbry has supplied. T. D. A. COCKERELL.

East Las Vegas, New Mexico, U.S.A., April 26.

Retention of Leaves by Deciduous Trees.

THE retention of leaves by beechen hedges referred to by your correspondent in NATURE, April 10, is by no means confined to those on elevated ground. It may commonly be observed in hedges of this tree whatever their situation. In Northumberland the beech is not infrequently used as a hedge, and always retains its leaves throughout the winter. Young beech trees also frequently retain their leaves, and by no means always in exposed situations. Indeed, the examples I have myself seen have been much more frequently in sheltered spots, as in plantations of older trees.

Nor is this phenomenon of deciduous trees retaining their leaves under certain conditions confined to the beech. It is, perhaps, equally common in the oak. Young oak trees in plantations may often be seen in the spring covered with brown and withered leaves. Larger trees may also sometimes be seen retaining the leaves on some of the *lower* branches, while the *upper* ones are bare. Travelling from Eastbourne to Victoria, soon after reading the above communication in NATURE, I noticed hundreds of young oaks covered with withered leaves. None of these were in elevated or exposed situations. Indeed, I am inclined to suggest, as an inference from the above facts, that it is rather the *protection* enjoyed by the trees which *enables* them to retain their leaves. In the one case the lesser height of the tree, and in the other the close intergrowth of the hedge, gives the wind less power to strip off the leaves. We can hardly consider that there is here a "protective device," unless on the part of the gardener who sets a beechen hedge to shelter his plants. G. W. BULMAN.

13 Vicarage Drive, Eastbourne, May 3.

WITH regard to the interesting communications concerning the retention of their leaves by young beeches, I beg to forward another possible solution. The beech is a "frost-tender" species, and early frosts, which would not rise high enough to affect large trees, would freeze the leaves of "small young" trees, thus preventing the formation of the abscission layer of cork at the base of the petiole. In such a case there is no reason why the leaves should fall off for a considerable time.

Leaves killed before the formation of this layer remain on the branch for an indefinite time, of which phenomenon pea-sticks cut in full leaf may serve as an example. P. T.

May 10.

THE RECENT VOLCANIC ERUPTIONS IN THE WEST INDIES.

NEWS of the terrible volcanic eruption in Martinique reached this country on Thursday last, and the details which have since become known have shown that an appalling disaster has occurred. St. Pierre, the chief commercial centre of the island, has been totally destroyed, and about thirty thousand people have perished. The eruption of Mont Pelée began on the night of Saturday, May 3, when large quantities of scoriæ and volcanic ash were thrown into the surrounding country. On Monday, May 5, a stream of lava is reported to have rushed down the side of Mont Pelée, following the dry bed of a torrent, and reaching the sea, five miles from the mountain, in three minutes. When the stream met the sea the water receded 300 feet on the west coast, returning with greater strength in a large wave.

Two days later, on May 8, a similar torrent of incandescent lava engulfed the town of St. Pierre. The following telegram describing the calamity was received at Paris from Fort de France on May 11, and was published in Monday's *Times*.

"The town of St. Pierre was destroyed on the 8th about 8 a.m. A terrible torrent of incandescent lava, from Mont Pelée, a volcano a few kilometres from the town, accompanied by a shower of fire, in a few seconds covered the town, and an immense furnace extended over the neighbouring coast, thus forming a line of fire from the village of Carbet to the town of Prêcheur. The effects of this volcanic torrent were felt as far as

Fort de France, and we received a shower of cinders and stones weighing seven to ten grammes. The whole island was covered three millimetres thick with cinders. The panic was general, yet relief was soon organised. The French cruiser *Suchet* went to the spot, as also other vessels towing boats, which soon returned, bringing terrifying news. The shore is unapproachable. The vessels in St. Pierre roads are on fire. The heat is extreme."

A later message from Fort de France, published in Wednesday's *Times*, says :—

"Access to the ruined town of St. Pierre has become more easy since the day before yesterday. At the Mouillage no signs of fire are now visible. Everything appears to have been rent and scattered as by a tornado. The iron gate of the Custom House remains standing. In the hospital the iron bedsteads are twisted, but bear no other traces of fire. The bed clothes and all other textile fabrics have completely disappeared. About 2000 corpses have been found in the streets. The central quarters of the town and the fort are buried under cinders to a depth of several yards. In the neighbourhood of the creek several houses remain intact, but the inhabitants were killed as if they had been struck by lightning, the bodies lying, sitting, or reclining in curiously diverse attitudes.

"Smoke is issuing from the crater of the volcano. Over the northern slope, as well as Basse Pointe, hover clouds of hot cinders, and flashes and rumblings are still distinguishable from time to time."

The Soufrière volcano in the neighbouring island of St. Vincent has also broken out in eruption. According to a *Times* telegram from St. Lucia, the northern district of St. Vincent, from Chateau Belair to Georgetown, has been devastated by an enormous flow of lava, destroying everything in its path. It is reported that both the large craters on St. Vincent are emitting enormous volumes of vapour, lava and hot ashes, and that small craters are bursting out everywhere. No vessel can approach the northern shore of the island on account of the intense heat and steam from the craters. Heavy ashes fell in great quantities on a steamer 250 miles from St. Vincent, and many masses of rock have fallen at Kingston. It is stated that sixteen hundred deaths have been caused in St. Vincent by the eruption.

This brief statement of the eruptions and their consequences contains the chief points of the news yet available. We are fortunate in being able to supplement the reports with an article by Prof. Milne upon the subject, and a summary in which he gives the sequence of events.

Sequence of Events.

April 19.—A very heavy earthquake occurred in Guatemala. It was recorded in the Isle of Wight, and might have been recorded anywhere in the world. It probably indicated a sudden adjustment in the orogenic fold of Central America, and a change in this fold possibly resulted in movements in the neighbouring fold represented by the West Indies, and hence the recent volcanic eruptions and earthquakes in that region.

April 23.—Mont Pelée showed a plume of "smoke."

May 3.—Mont Pelée not only "smoked," but at night was lighted up by the incandescent lava within its crater.

May 4.—Mont Pelée covered the surrounding district with ash.

May 5.—A stream of mud and lava were erupted and engulfed a sugar factory, twenty-three persons being buried. The sea receded 300 feet.

May 6.—A Government Commission issued a reassuring report.

May 7.—About 11 p.m. (Martinique time) a small earthquake from a very distant origin was recorded in the Isle of Wight, Edinburgh, and at other stations.

May 8.—At 8 a.m. "the rain of fire" destroyed St. Pierre. Ships were burned and sunk by a shower of rocks and heated materials, which poured down for about fifteen minutes. At Fort de France, twelve miles distant, these stones were the size of walnuts.

This eruption still continues, but on the 10th it had so far decreased that the site of St. Pierre was explored, but no living beings were seen.

The eruption of La Soufrière in St. Vincent commenced on Monday, May 5, and on May 7 the eruption was violent.

It would therefore seem that these two eruptions were simultaneous, and may have been brought about by a common cause.

Martinique, which, the *West India Pilot* tells us, is 35 miles in length and 7 to 16 miles in breadth, "is very lofty and irregular in height, and may be readily distinguished by three remarkable mountains of different forms, rising far above the general chain which runs through the whole of the island from N.W. to S.E., and may be seen about 45 miles off. The most northern of these is Mont Pelée, 4428 feet above the sea, rising nearly 4 miles to the south of Cape St. Martin, and its summit, when seen from a distance, appears rounded, and presents nothing remarkable."

It seems to be an irony of Nature that the most dangerous creations should so frequently simulate the appearance of that which is quite ordinary.

Prior to A.D. 79, Vesuvius was in its appearance even more innocent than Pelée. Spartacus and his gladiators camped within its crater, which, Plutarch tell us, was to a great extent covered with wild vines. On its flanks were cultivated fields, at its base the wealthy and populous cities of Pompeii and Herculaneum. If we except a few slight shocks which preceded the burial of these two towns, there was nothing to indicate the terrific outburst by which this was accomplished. The mountain, which was "nothing remarkable" in its appearance, suddenly exploded, there was a rain of ash, and the surrounding country became a desert.

Another illustration of the awakening of a slumbering Titan was Krakatoa. After a rest of 200 years, this mountain, on Sunday, May 20, 1883, gave symptoms of unrest by an eruption accompanied by shakings and roarings, which were loud enough to be heard even at a distance of 100 miles. Then for a few months there was comparative quiescence until August 26, when a crater opened near sea level and the challenged ocean poured in upon internal fires. The story of the battle which ensued, with its fearful detonations, which were heard at Rodriquez, 3000 miles distant, the appalling darkness created by black ash suspended in the atmosphere, the finer particles of which belted our globe and gave rise to brilliant and peculiar sunsets, the great sea waves which were formed to devastate surrounding coasts and destroy 36,000 lives, forms a well-known chapter in the history of vulcanology.

Pelée, the Hawaiian goddess who from her well of fire serves out molten rock for the consumption of those with whom she is angered, gives as spin drift from her molten fountains tresses of her glassy hair. Possibly the Pelée of the Antilles, although she has not sought an encounter with the oceans, may give to our atmosphere exhalations and glassy particles, the evidence of which will be seen in meteorological observations.

A third illustration of a mountain which to all who knew it was in its appearance as innocent as Primrose Hill, but without any premonitory warnings suddenly blew itself to pieces and changed the topography of the surrounding district, was Bandaisan, in central Japan. When, in 1878, the writer visited this mountain, to clamber through woods and vines with which its sides were covered and pass over a grass-covered depression at its summit where deer were browsing, the only indications that this round-headed hill might be included in the list of active volcanoes were that at its base there were some hot springs, whilst on its flanks a few pieces of scoria were seen. Ten years later, this apparently

peaceful mountain drove sixteen hundred million cubic yards of itself to such a height that many of the falling fragments struck the ground with such velocity that they were buried out of sight.

To know the extent to which the phenomena accompanying the eruption of Pelée find a parallel in those exhibited by her predecessors will be determined in the future. The probable loss of life, which it is to be hoped has been over-estimated, is given at 40,000. Whatever this number may be, it has been suggested that the same might have been reduced had the inhabitants of the stricken district taken warning from the slight earthquakes by which the great eruption was preceded. But may we not ask whether small earthquakes are not so frequent in the Windward Islands that were the inhabitants to fly with every tremor the Antilles would be depopulated?

Although the last great eruption of Pelée, which was one of frightful violence, occurred in 1851, statistics which do not take account of mere tremors credit the Island of Martinique, in an interval of twenty-six years, with 148 disturbances, whilst the Lesser Antilles generally are, during the same interval, credited with nearly 1200.

That volcanic outbursts are usually preceded by slight earthquakes is well known. How very slight these may be is testified by the tall and not too substantial buildings in Naples near the base of the almost continually erupting Vesuvius. Unfortunately, the occurrence of slight earthquakes is very much more frequent without, rather than with, volcanic outbursts. Many of the 1000 earthquakes which are annually recorded in Japan, two or three of which would shatter a London, are felt round the base of volcanoes, but it is only on rare occasions that they have been followed by disaster. Could science devise a means by which increasing pressure beneath a volcanic area could be measured, or could the crust of the same be rendered transparent, until familiarity ended in contempt, such areas would in all likelihood be sparsely populated; but so long as we cannot distinguish between the shakings which announce the abortive attempts of volcanoes to establish an opening and those tremblings and gurgitations which precede attempts that are successful, people will go on living as before.

One writer predicts great storms to follow the eruption. In August, 1891, a hurricane passed over Martinique, to be *followed* by an earthquake. The hurricane months for Martinique are July, August, September and October, when no doubt we shall have records of hurricanes both before and after earthquakes.

In considering the probable cause of this West Indian disaster, attention is drawn to the fact that the Lesser Antilles as seen on a chart are a group of islands running approximately from south to north, forming the outcrops of a suboceanic ridge. The western side of this ridge is steeper than the eastern, with the result that off Martinique, for example, at a distance of 5 or 6 miles there are soundings of 1200 fathoms, whilst on the opposite side such depths are not even found at distances of 50 miles off shore.

The steepness of this fold is such that earthquakes might be expected to originate along its western frontier, whilst volcanoes would occur along its ridge. Now it is chiefly along this western frontier that the cables pass. Those of Martinique, of which there are six, radiate from Fort de France. One goes northwards 12 miles, to end at the ill-fated St. Pierre. Three others also pass northwards to Guadeloupe, Dominica and St. Thomas. Another goes southwards to Paramaribo, and the last to St. Lucia, St. Vincent and other places.

Notwithstanding the existence of so many cables, communication with Martinique, and later with St. Vincent, was interrupted. At St. Pierre the cause of this was no doubt due to the avalanche of mud and lava which overwhelmed the town and roadstead. The cause of interruptions out at sea would be sought for in seismic convulsions, but of such disturbances of any magnitude there is no evidence. Since 8 a.m. (Martinique time) on the 8th, when St. Pierre was overwhelmed, until the 11th, seismographs in Great Britain have been at rest. That *small* earthquakes occurred is known, and it is just possible that some of these caused landslides sufficient to bury and damage the cables running along and across the steep suboceanic slopes described.

The cause of these earthquakes and the volcanic outbreak of Mont Pelée and of the Soufrière in St. Vincent—at which the last great eruption took place in 1812—probably results from some widespread rearrangement in the fold, the ridge of which is represented by these islands. The geological evidences pointing to elevations and depressions amounting to as much as 12,000 feet, and all within late Tertiary times, are found in the Barbados and other parts of the West Indies. If we assume that earthquakes are accelerations in these orogenic processes, and volcanic outbursts indicate that pressure has been relieved along the foldings they create, one inference is that the terrible disasters in the West Indies announce that a change has taken place in the configuration of the ridge which above the surface of the water is known as the Lesser Antilles.

Whatever may be the scientific inferences in connection with the great catastrophe, the situation it has created, which Byron might describe as one in which

> "Sires have lost their children, wives
> Their lords, and valiant men their lives,"

commands the heartfelt sympathy of the civilised world.

J. MILNE.

DOES CHEMICAL TRANSFORMATION INFLUENCE WEIGHT?

IN NATURE (vol. lxiv. p. 181, 1901) I directed attention to experiments by Heydweiller (*Drude Ann.*, vol. v. p. 394) from which he inferred that some chemical transformations, such as the solution of copper sulphate in water, were attended by real, though minute, changes of weight, and I pointed out certain difficulties involved in the acceptance of this statement. In connection with another subject, it has lately occurred to me that such changes of weight would really be in opposition to the laws of thermodynamics, and I propose now briefly to sketch the argument from which this opposition appears.

It is known [1] that by suitable arrangements the dissolution of salt may be effected reversibly at a given temperature. During the process, a certain amount of work is gained and a certain amount of heat at the given temperature has to be supplied. In the reverse process, of course, an equal amount of work has to be performed and an equal amount of heat is recovered. The temperature being given, these operations are not affected (it is assumed) by the height above the earth's surface at which they may be supposed to take place.

Conceive now that the temperature is uniform throughout and that the materials are initially at a low level and in one state (A). Let them be raised to a high level and there be transformed into the other state (B). Subsequently let them be brought down to the low level and transformed back into state A. The reverse transformations above and below compensate one another thermodynamically, and *if the weights are the same in the two states*, so do the operations of raising and lowering. But if the weights in states A and B are different, the cycle of operations may be so executed that *work is gained.*

[1] "On the Dissipation of Energy," NATURE, xi. p. 454, 1875; "Scientific Papers," vol. i. p. 238.

Such a difference of weight is therefore excluded, unless, indeed, hitherto unsuspected thermal effects accompany a rising or falling against or with gravity. It is scarcely necessary to say that we are not here concerned with the differences of temperature and pressure which may actually be met with at different levels over the earth's surface.

There are many chemical transformations which cannot easily be supposed to take place reversibly. But this, though it might complicate the statement, does not affect the essence of the argument; and the conclusion appears to be general.

If the reasoning here put forward be accepted, it increases the difficulty of admitting the reality of such changes of weight as have been suspected, and it justifies a severe criticism of experimental arrangements. In my former letter I pointed out a possible source of error.

It is to be hoped that the matter may soon be cleared up, for it is scarcely creditable to science that doubt should hang over such a fundamental question. But for my own part I would wish to say that I fully recognise how much easier it is to criticise than to experiment.

RAYLEIGH.

UNIVERSITY COLLEGE AND THE UNIVERSITY OF LONDON.

AN influential meeting was held at the Mansion House on Friday last in support of the fund for higher University education and research in London, with special reference to the incorporation of University College in the University. The Lord Mayor presided, and the company present included many who have contributed to national progress in various ways and are anxious that adequate provision shall be established for future advance.

The appeal made by University College was described in our issue of May 1 (p. 10), and at the same time a brief statement was made of the needs of the University and its Colleges. The University can only become a living organism when the Colleges connected with it are actually part of its being. The incorporation of University College would be the commencement of this desirable development, and the ultimate structure would be on a scale worthy of the greatness of our great metropolis.

We are glad to see that the Duke of Devonshire, in his speech at the Mansion House, made special reference to some of the points to which attention was directed in our article. He explained that though the University of London has statutory powers to teach, it has not the material means of teaching, and cannot take part in the extension and advancement of knowledge until placed in possession of buildings and resources for carrying on the work of higher education. The provision of funds for University College thus means the strengthening of the University itself, for by incorporation the senate would acquire complete control over the whole resources of the College, and would be able to carry on the work of the various departments under better conditions than at present are possible.

The urgent need for liberal endowments for higher education in London was stated in our recent article and has often been put forward in these columns at other times. The educational wants of London are, indeed, almost a discredit to the rich citizens, and the inadequate provision made for higher education generally shows that the State does not realise the importance of such studies as factors in national progress. But though the State does little or nothing for those who are making knowledge, the Duke of Devonshire expressed himself as aware of the value of extending the resources of education and research, and other speakers at the Mansion House (including the Lord Mayor) took the same view. Referring to the necessity of giving greater consideration than has hitherto been done to the requirements of the country in this respect, the Duke of Devonshire said:—

"Within the last half-century the gigantic strides which have been made in the discoveries of science have brought about great changes in our requirements as to higher education. It is now recognised that in all professions and industries success must be dependent on a knowledge of scientific principles and on the trained capacity to apply those principles. The Universities are no longer a necessity for one class alone, but the welfare of the whole nation demands that we should seek through all classes men of high intelligence, and, having found those men, that we should equip them with the highest training. These changes in the requirements of higher education found us in this country to a certain extent unprepared. As a nation we cannot be said to have been quick to recognise the necessity of corresponding changes in our higher University training. The older Universities of Oxford and Cambridge have recognised the necessity and have made great efforts to equip themselves with the necessary machinery, but they have found themselves hampered by a want of the necessary resources.

"But, even if complete satisfaction could be given to the claims of the older Universities, still that would not suffice for our national necessities or meet the requirements of present conditions. Our success as a nation depends upon the possession of trained brains, and these we cannot get in sufficient number from any one class, and the older Universities cannot supply the number of trained men we require for our national industries. In all the great towns and industrial centres, University institutions properly equipped and properly endowed are now a necessity, and this need has already received a considerable amount of local expression. I need only give you the instance of the University of Birmingham and the movement which is now taking place in Liverpool for the establishment of a separate University there. But in London, owing to its size and the absence of what may be called local patriotism, the University movement has up to the present time failed to receive that support which might be expected from the wealthiest city in the world. But now, to-day, an opportunity is afforded to the citizens to repair any past neglect, and to create for London a University which shall be worthy of the capital of the Empire and adapted to the special needs of the metropolis of the Empire."

Resolutions were afterwards carried in support of the scheme of incorporation, and urging citizens of London to make a generous response to the appeal for one million pounds to endow and equip University College with a view to its incorporation. It remains to be seen whether London is sufficiently jealous of its honour and supremacy to make the University bearing its name rank with those of Europe and America.

THE CULTURE OF GREENHOUSE ORCHIDS.[1]

BEFORE passing judgment on a work of this kind it is only fair to the author to attempt to ascertain his object in writing it, so that a fair conclusion may be arrived at as to how his object has been attained and the use of the resultant work to those who consult it, for that is the main consideration.

In the first few lines of the preface, Mr. Boyle very definitely gives his reason for writing the book. He says: "The literature of orchidology is voluminous in these days. But a book written 'by an amateur for amateurs' is still needed." That was a very good reason. Every new work on orchids, or on any other special subject, tends to increase the knowledge and growth of the subject dealt with, and as the devotees to orchid culture are mainly recruited from the amateurs commencing in a small way, a work written by an amateur, and especially by such a pleasant and entertaining writer as Mr. Boyle, who has the art of conveying instruction with amusement, must be of the highest value.

[1] "The Culture of Greenhouse Orchids." By Frederick Boyle. Pp. xii + 231. (London: Chapman and Hall, Ltd., 1902.) Price 8s. net.

The handy little volume, extending over two hundred and thirty pages, has three excellent coloured plates and fifty illustrations of single flowers of cool-house orchids,

FIG. 1.—Odontoglossum Crispum Pittianum, showing the widest departure from the normal white form. The sum of 750*l.* was offered for this plant.

reproduced from photographs by Colonel F. C. Taylor. The book, though useful as a work of reference, will be found to give the best results to the amateur just beginning orchid culture, or who has been pursuing it with indifferent results, if he repeatedly peruse it from beginning to end. Thus he will have a sound basis on which to continue his work, freed from the struggles and failures which the unaided amateur must expect, and the sorrows the past experience of which Mr. Boyle justly advances as a reason why he should be able to write a book which would be useful to those who contemplate following him as amateur orchid cultivators—a pastime of the greatest interest and pleasure if reasonably followed.

The work opens with six lengthy and instructively written articles, setting forth the general principles of orchid culture and matters relating to it, after which throughout the remainder of the work follow the enumeration of the genera and species suitable for culture in the greenhouse, together with cultural remarks and much information relating to each, all of which, having passed the scrutiny of that well-known and clever expert, Mr. Joseph Godseff, have a sufficient guarantee of excellence.

On testing the question ample proof is obtained. If but for the articles on *Coelogyne cristata* and on Oncidiums for the cool-house, the perusal of the work might well be recommended. In the case of *Coelogyne cristata*, one of the most beautiful and easily grown orchids when treated as Mr. Boyle advises, there are few species which give more unsatisfactory results to the budding amateur growing it by his own judgment. Even experienced growers in large establishments often have their plants with the shrivelled bulbs which are cited as to be avoided by the method prescribed. In the matter of the Oncidiums enumerated, the mere direction that they are to be grown in a cool-house is almost sufficient to ensure success, for they are more often than not grown in too high a temperature and killed in consequence. And so on throughout the book; even the enumeration together of the species which can be successfully grown in a greenhouse, to say nothing of the excellent cultural details, makes it of great value, for it saves the amateur from attempting things which require more heat than he can give—a mistake which causes many small amateur collections to look shabby and annoy and disgust the owner, who has probably taken more pains to bring about that undesirable state of things by working on unsuitable subjects than he need take to ensure a delightful success on the lines set forth in Mr. Boyle's book.

But from the critic the book calls for some remarks on points which luckily do not much interfere with its general usefulness. In the preface and following articles, Mr. Boyle makes much of his desire to advance the new Belgian culture of orchids in oak-leaf mould, or terre de bruyère, but in the progress of the work he only places it as an alternative method, wisely placing the well-tried British method of potting in peat fibre and sphagnum moss in the first place. It should be remembered that there is a vast difference between the Belgian collections, with large numbers of a few species only, and many of the British collections, which include a few of each of a large number of species. Then there are climatic and other differences; and above all it should be said that one of the largest and oldest and some of the smaller Belgian orchid growers, after experiment, will have nothing to do with it. In Great Britain the question is on trial, and while in some places there are excellent specimens grown in leaf-soil, in others it has been tried and abandoned.

FIG. 2.—Odontoglossum Cervantesii Decorum.

Again, when touching on the use of manures something more definite than general remarks might have been used —the "yea or nay" promised in the preamble—or the

small amateur who is induced to experiment will surely find himself in trouble.

In the chapter "Orchid Names," the author follows the popular lead by finding fault with the existing orchid nomenclature, and with the inevitable result that he is unable even to hint at a better method than that for which we have to thank a long line of patient and clever men who have been working on the subject in all ages since the classification of plants began. It should be remembered that the question is not as to whether the name is good or bad Latin or Greek, expressive or not expressive, but that it is intended as a means of identifying the plant in every civilised quarter of the globe, an end which no system of popular names could accomplish, but which has worked under the present system of scientific names in a marvellously satisfactory manner. To apply it to his own case. Deprived of the scientific names he finds fault with, Mr. Boyle's book would have been impossible in its present useful form.

Orchid culture cannot be reduced to an exact science. Each operator has to adapt his methods to his convenience, but in order to know how to meet his difficulties and to overcome them, Mr. Boyle's book will be found invaluable. In some cases the prices at which the plants may be obtained are also given.

THE ROYAL VISIT TO THE UNIVERSITY OF WALES.

THE installation of the Prince of Wales as the second Royal Chancellor of the University of Wales is associated with an important epoch in the development of university education in North Wales. When the University College of North Wales was founded in 1884, it would have been difficult to find a more ideal situation for a centre of university education than the Penrhyn Arms Hotel at Bangor, which possessed ample accommodation for existing requirements. But eighteen years ago, Hertz's realisations of Maxwell's theory of electric oscillations, culminating in wireless telegraphy, did not exist; the existence of Röntgen and other rays had not been anticipated; no argon was known to exist in our atmosphere, no helium in our earth; the liquefaction of the more permanent gases was regarded as a mere classical experiment, impossible on a large scale; even in mathematics, the fertile theory of groups was almost untrodden ground. Taking also into account the increase in the number of students in the eighteen years from 55 to 320, it is small wonder that new buildings with more modern equipments have now become indispensable for the further progress of the College. These needs bid fair to be soon met by the recent generous gift on the part of the City of Bangor of a new plot of ground 10·6 acres in extent, about 6·6 acres of which are available for building purposes, on a site which, in the opinion expressed by Principal Reichel, "any university College in the kingdom might well envy." This gift represents, for the City of Bangor, the equivalent of a gift of one million pounds from the citizens of a wealthy town comparable with Liverpool.

The smallness of the population of Bangor and the absence of the large wealth-producing industries of our midland towns are a sufficient guarantee that the new College need never fear the disturbing influences of electric trams and the smoke and din of factories which have afforded such an obstacle to scientific research in wealthy and thickly populated manufacturing centres.

The University congregation was held, not at Bangor, but at Carnarvon, where the large pavilion had been transformed into a senate house. The lavish display of bunting at Carnarvon and subsequently at Bangor; the gowns and hoods of graduates, extending over the whole range of colours from violet to red, and the presence of large contingents of students from Aberystwyth, Bangor and Cardiff, including a considerable proportion of "sweet girl undergraduates" in caps and gowns, all contributed to the festivity of the scene. Even the mountain ranges of Snowdonia were clad in white hoods of snow rarely seen in May. The actual installation ceremony having been completed by the presentation of the key of the University seal and a copy of the statutes to the Prince as Chancellor, addresses were read by Dr. Isambard Owen and Principal Roberts on behalf of the University court and senate, and addresses were also presented or read on behalf of several other bodies, including the guild of graduates. The Prince in reply, after referring to the work done by teachers and students of the Welsh University, laid special stress on the encouragement given to post-graduate and scientific work, and the fact that it is by the work done in after life by its graduates that the reputation of a university is really made. The Chancellor then admitted the Princess of Wales to an honorary degree in music and proceeded to the conferment of honorary degrees, in which science was represented by the Earl of Rosse, the recipients being presented by Vice-Chancellor Roberts, of Aberystwyth. The intervals in the proceedings were filled by part songs sung by a well-trained choir, and at the conclusion the problem of transporting the guests to Bangor was solved with remarkable success. Here luncheon was laid for six hundred and fifty in a marquee pitched close to the new site, under the chairmanship of Lord Kenyon. In his speech, the Prince of Wales once more struck a chord which he had already sounded at the National Physical Laboratory in referring to his recent tour and his experience of the work done in universities across the seas in bringing intellectual ability to the front and rendering it available for the public service. This line of thought was ably echoed by Principal Reichel in his remarks that "The idea, which at one time was not uncommon, that intellectual training is unfavourable to action is now happily becoming discredited at home; on the Continent it has long ago perished. . . . The function of provincial university colleges is, in short, to train up a more vigorous and efficient race, fitted to meet the heavy demands which the course of world events is making on the inhabitants of these islands, a race of more efficient thinkers, of more efficient workers, and if the necessity should arise, of more efficient fighters." Principal Reichel further announced the receipt of an offer of twelve scholarships of 30*l.* for three years from Sir Alfred L. Jones, of Liverpool. It was also announced that the town of Cardiff, like Bangor, has presented its University College with a new site.

The next item was the visit of the Prince and Princess to the present College, where a guard of honour was formed by the College volunteer corps. Interest naturally centred round the museums and laboratories. The College possesses a very fair zoological museum, and it is proposed to establish in connection with the same department a marine station where problems connected with the fisheries of the North Wales coast can be studied systematically. Already efforts have been made to arouse interest in the fishing industry by popular lectures. Most of the work of the College in agriculture has been hitherto carried on at a farm right away near Llangefni, but the College is now indebted to Colonel Platt for an experimental farm in a much more accessible situation near Llanfairfechan. Of other recent developments on the science side, we note the Drapers' Company's temporary endowment of a school of electrical engineering, a school which is bound to develop when a university training is, as it should be, insisted on in this country as an indispensable qualification for every electric engineer. The organisation of a department of mining is also, thanks to the support of local bodies, approaching completion. A recent gift from Mr. George Rae for the purpose of

providing teaching in banking and finance affords evidence that the commercial side of modern university education has not been overlooked, and a further gift from the trustees of the late Sir Henry Tate has been announced.

The last item in the Royal visit to Bangor was the visit of the Princess of Wales to the University Hall, where an enthusiastic reception from the women students, assembled in cap and gown under Miss Fowle, was awaiting the Royal party.

If there is one function on which the University of Wales, in common with other universities, will have to lay ever-increasing stress, that function is the dissemination in the less accessible parts of the Principality of those internationalising influences which are now bringing all parts of the civilised globe into closer touch with each other. The deliberations of English-, French- and German-speaking science workers are daily becoming more and more international in character, and this influence is spreading gradually down the educational ladder. The late Mr. Cecil Rhodes's scheme for fostering the international spirit in Oxford is still in our minds, and it may be confidently hoped that modern and well-equipped University College buildings both in North and South Wales will do much to promote that educational influence which may so well be summed up in the word "internationalisation."

G. H. BRYAN.

THE IRON AND STEEL INSTITUTE.

THE annual meeting of the Iron and Steel Institute was held on May 7 and 8, and a short report of the proceedings is subjoined. At the annual dinner of the Institute, on Wednesday of last week, Mr. Arnold-Forster made a few remarks upon the duties of the State towards science, and the necessity for the introduction of scientific organisation and method in all departments and works of a progressive character. We give his speech as reported by the *Times* :—

Mr. Arnold-Forster said that however little he might contribute to the Government in any other matter, he did contribute in full measure great respect, great admiration and great reverence for science and scientific organisation. By scientific organisation he meant the application to the ordinary work of everyday life, the work which had been thought out and coordinated by students of science. In this country we were probably behind almost every other great country in the recognition of the great truth that science had a lesson for everyone in producing economy and efficiency by the application of a scientific method. There was a time when the duty of the State to take its part in ordering the work of the nation was more clearly recognised and acted upon than it was now. The enormous attention which was given to regulating our coinage and to giving us a system of weights and measures formed a considerable part of the earlier economic history of this country. But when we had accomplished those one or two rudimentary duties, the State appeared to think that nothing more could be accomplished or was to be expected from it as the administrator and as the instrument to apply in the teaching of science. But the time had gone by when we could afford any longer to fail to recognise the direct duty of the State to the country in the matter of organising on some scientific principle many of the most important departments of our scientific life. Governments were now so enlightened that they could interfere in scientific matters with certainty of producing the results which they desired. It should be insisted upon that in every department which came within the purview of the Government there should be scientific coordination and organisation. He would not speak of weights and measures—though there, indeed, a wise Government might step in—but there was the kindred branch of scientific application about which he would say a word—namely, standardisation and the uniformity of tests. In that regard we were behind the Continental nations. He had been studying the publications of the great Continental nations for the coordination of tests of materials and the institution of standard dimensions, and the conviction had been forced upon him that we had already allowed opportunities of cooperation to go by which we ought to have seized. He was glad that at the eleventh hour the Iron and Steel Institute, the Institution of Civil Engineers and the Institute of Naval Architects had taken up the work. He wished every success to it. The French Government were standardising their railway material, but nothing corresponding to that existed in the records of our Governmental arrangements. In inspecting a steel works recently he found that in the matter of tensile strength for steel there was one test for the Admiralty, another for the War Office, another for the Board of Trade, another for one set of railway companies, and another for another set (the Board of Trade recognising neither), another for the Egyptian Government, another for the Indian Government, and another for the whole of the Continent of Europe. That was absolutely crazy. It was like measuring pints by fourteen different kinds of pint pots. They were all sinners in that respect—all the departments—because it ought not to be allowed. He urged that scientific societies should forward the work of standardisation as forcibly as possible. Already in the Admiralty great strides were being made, thanks to Sir William White, and already they had succeeded to some extent in the standardisation of electrical appliances. They had also standardised in the whole of the gunnery branch, and were now endeavouring to do so to a much larger extent in the whole of the fittings of the ships. When the Iron and Steel Institute and kindred associations had made up their minds as to what was the true method of standardisation they should go boldly to the Government and ask them to undertake that within a definite time all Government specifications should be within the terms of that standardisation. He was not unaware that there was a danger in standardisation, that one must not stereotype too closely, and must not interfere with improvement by solidifying all patterns; and therefore he trusted that they would insist upon it that the Government should be the cooperators in the work in which the Iron and Steel Institute and kindred societies must be the kindred spirits. In conclusion, he said that we had been too modest in this country of advancing the claims of science. What was done for applied science in every other civilised country should make us ashamed of the pittances doled out in England, which were supplemented to the extent of 99 per cent. by private charity, for the purpose of performing those elementary duties of coordinating the scientific part of this country's life. He believed that if the scientific associations took a high line in the matter the country would support them right through.

Other speakers at the dinner were Sir Alfred Hickman, Admiral Sir N. Bowden-Smith, Sir Bernhard Samuelson, Lord Raglan, Lord Blythswood, Sir Christopher Furness, Sir W. C. Roberts-Austen, General Sir John Maurice, Sir Norman Lockyer and the president.

At the annual meeting of the Institute the chair was occupied by the president, Mr. W. Whitwell. The Bessemer gold medal was presented to His Excellency F. A. Krupp, of Essen. The Andrew Carnegie medal was awarded to Dr. J. A. Mathews for the research described in his report; and Andrew Carnegie research scholarships, each of 100*l*., were awarded to Messrs. O. Boudouard (Paris), W. Campbell (New York), A. Campion (Coopers Hill), P. Longmuir (Manchester), E. Schott (Berlin) and F. H. Wigham (Wakefield). The following are the chief points of the papers read :—

In the first paper, Mr. J. H. Darby embodied the results of experiments made with the object of improving the quality of coke by compressing the fuel before coking. The net gain in production of coke per oven was found to be between 10 and 12 per cent. in favour of the compressed charge.

Mr. J. Thiry read a paper on the recovery of by-products in coke-making. He gave some striking figures showing the profit and economy derived from this method of coke manufacture, and described the most recent form of the Otto-Hilgenstock coke oven. These two papers gave rise to an interesting discussion, in which Sir Lowthian Bell, Sir Bernhard Samuelson, Dr. Ludwig Mond and other members took part.

Mr. A. McWilliam and Mr. W. H. Hatfield described an exhaustive research dealing with the control of the silicon in the acid open-hearth bath. The experiments were made in a 25-ton furnace at Sheffield. The results detailed, showing the influence of the composition of the slag on the elimination of impurities from metal under an oxidising influence, seem to point to the necessarily very acid slag produced being beyond the point at which silicon can be oxidised, for it would appear that not only can phosphorus and sulphur not be oxidised in an acid-lined vessel in the presence of an acid slag, but that silicon is not oxidised to below a certain percentage when the acidity of the slag is beyond a certain point. The authors have thrown light on a subject still requiring further elucidation, namely, the relation between the composition of the slags and the type of oxidation or even reduction taking place, and they in particular have not seen recorded this exact balancing of the composition of the slag, so as at will to eliminate or reinstate small amounts of silicon and manganese while the carbon continues steadily to fall. A well-sustained discussion followed, in which the value of the paper was generally recognised.

Mr. H. Allen described a new system of cooling blast-furnace tuyeres in such a manner as to prevent the leakage of water into the furnace crucible. The meeting then adjourned until May 8, when the secretary, Mr. Bennett Brough, presented the report of the committee appointed to ascertain whether it would be possible to make the terminology of metallography less complicated and more precise. This comprises a glossary of the more important terms used by authors of memoirs dealing with the subject, with the exact equivalents in French and German. Care has been taken to exclude all controversial matter, and, in cases where a definition is not quite universally accepted, to quote the definition given by its respective author.

The next paper, by Prof. J. O. Arnold and Mr. McWilliam, was of a highly controversial nature. The conclusions arrived at in the paper were as follows:—The clear and definite constituents of hardened steel are (*a*) hardenite, $Fe_{24}C$, of which the whole mass consists, only in the case of 0·89 per cent. carbon steel; (*b*) ferrite, Fe, which segregates more or less in unsaturated carbon steels in spite of the rapid action of quenching; and (*c*) cementite, Fe_3C, which segregates more or less in supersaturated steels in spite of the rapid action of quenching. The indefinite portions of hardened steels consist in unsaturated carbon steels of hardenite containing more or less unsegregated ferrite, or in supersaturated carbon steels of hardenite containing more or less unsegregated cementite. Martensite is not a constituent, but a crystalline structure developed at high temperatures. It is marked in saturated carbon steels by preferential etching lines, in unsaturated carbon steels by striæ of ferrite, and in supersaturated carbon steels by striæ of cementite. The existence of the constituents sorbite, troosite and austentite is extremely doubtful. Students of micrographic analysis should guard against apparent or false constituents really due to optical causes or to obscure polishing or etching effects. The authors' investigations detailed in this paper have been strictly confined to pure iron and carbon steels such as are produced in the best crucible practice. The views expressed by the authors were opposed by Sir W. C. Roberts-Austen, Mr. J. E. Stead and other members.

Dr. J. A. Mathews' paper on a comparative study of some low carbon alloys, which was next read, contained the results of a research undertaken in New York by the author as Andrew Carnegie research scholar to ascertain the effects of various elements upon iron. The elements studied were nickel, chromium and molybdenum. Prof. Arnold took exception to this paper on the ground that no reference was made to his own work on the same subject.

Mr. H. Kilburn Scott presented an elaborate description of the iron ores of Brazil. The quality of the mineral and the great size of the deposits will, the author is convinced, enable Brazilian iron to take a leading position in the market. Some valuable additional details were furnished by Mr. H. Bauerman.

Mr. P. Eyermann, of Benrath, near Düsseldorf, submitted a paper describing a proposed method of combining the blast furnace and the open-hearth furnace. The novel feature consisted in the employment of blast-furnace gas in the open-hearth furnace, in arrangements for improving the quality of the gas and in the application of air nozzles to one of the hearths.

Mr. Axel Wahlberg, of Stockholm, communicated an important paper on Brinell's researches on the influence of chemical composition on the soundness of steel ingots. The percentage of carbon and the casting temperature, which have hitherto been regarded as the agents responsible for the presence and position of blow-holes, are to be regarded as exercising a secondary influence. The principal cause is the percentage of silicon and manganese, and in some cases of aluminium, contained in the ingot metal at the moment of casting. In the discussion, Mr. C. P. Sandberg pointed out that some of the results given by Brinell had been anticipated by himself in a paper read ten years ago.

From the investigations recorded in Baron Jüptner's paper on the sulphur contents of slags, the following conclusions are drawn:—If during metallurgical processes a state of equilibrium is established between the slag and the contiguous metallurgical product under treatment, the sulphur distributes itself between the two in a constant ratio (the coefficient of distribution), the value of which is dependent on the composition of the two phases under consideration and on the temperature. In general the value of these coefficients of distribution increases with the basicity of the slags. It increases also apparently with the proportion of lime and manganous oxide (probably also with that of ferrous oxide and zinc oxide) in the slag. In the case of alloys of iron, the value of the coefficient of distribution increases, and very considerably, with increasing percentages of carbon and manganese and with diminishing percentages of phosphorus. The influence of the composition of iron alloys on the coefficient of distribution increases and diminishes with the increase or decrease of the basicity of the slag. The same law holds good with respect to the influence of a higher percentage of lime and manganous oxide in the slag. The conclusion contained regarding the effect of the composition of iron alloys may be explained by the supposition that the capacity of manganese, and perhaps also that of iron carbide, or at least of iron rich in carbon, to absorb sulphur is very low, while, on the other hand, that of pure iron and phosphide of iron is very high. These facts show that in metallurgical operations in general it is impossible to eliminate entirely from the product the whole of the sulphur contained in the charge. The extent to which desulphurisation can be carried depends upon the coefficient of distribution—that is, upon the composition of the two phases occurring during the process in question. On this account the desulphurisation of irons rich in carbon and manganese (ferromanganese and pig iron) is more complete than with irons low in carbon and manganese, such as those produced by the open-hearth and Bessemer processes. In the Bessemer process, the phosphorus exercises an additional counter-influence to the desulphurisation; but this appears only to be possible when the phosphorus has largely decreased, in which case, however, the carbon and manganese have also almost entirely disappeared. In order, therefore, to keep down the sulphur to the lowest possible margin in iron, which is very low in carbon and manganese, there remain only two courses open (since the basicity of the slag cannot be increased beyond a certain limit), viz. (*a*) either in the selection of a charge that contains the least possible sulphur, consisting of pure iron or of iron that has been desulphurised in the mixer; or (*b*) by repeated removal of the old slag and the formation of new slag. In this connection a mixer could be employed with good effect, since this not only supplies a raw material lower in sulphur, but its use necessitates the removal of the mixer-slag and the formation of new slag. It is by no means impossible, especially with a falling temperature, that a third phase, a mixture of oxides and sulphides, may occur in conjunction with the slag and metal. This phenomenon seems to occur during certain segregations.

In a paper on the chemical and physical properties of carbon in the hearth of the blast furnace, Mr. W. J. Foster showed that by increasing the temperature and diameter of the hearth, more carbon would be exposed to the oxides, with proportionally less interruption by the gases that are decomposed in the neighbourhood of the tuyeres; hence more carbon would be converted into carbon monoxide in the hearth per unit of air introduced at the tuyeres, and consequently an increased rate of driving and economy would be the result.

The making of a fixed gas from wood for service in the gas engine or in the manufacture of steel is in some localities desirable. Mr. James Douglas, of New York, was induced, therefore, to give a detailed account of the use of a fixed gas, made in a modification of the Loomis gas producer in Mexico. The meeting terminated with the usual votes of thanks. The autumn meeting of the Institute will be held at Düsseldorf on September 2 to 5.

GEORGE GRIFFITH.

THE news of the sudden death of Mr. George Griffith, Assistant General Secretary to the British Association, came as a shock to all who were acquainted with his vigorous personality. On the afternoon of May 7 he left the office of the British Association apparently in his usual health, and took his place in the train from Baker Street Station for Harrow. Scarcely had the train started when he was seized with an attack which ended fatally in a few minutes.

Griffith's career was divided into three periods—his Oxford life, his long tenure of an assistant mastership at Harrow School, and the last twelve years of his life occupied with his duties as assistant general secretary of the British Association.

His career at Jesus College, Oxford, was a brilliant one. After taking honours both in classical and mathematical moderations, his name appears, alone, in the first class in the final school of natural science in 1856. For the next eleven years he resided at Oxford, where he married a daughter of Mr. A. H. D. Acland Troyte. Toward the latter end of this period he was appointed deputy for the professor of natural philosophy, from which position he was summoned in 1867 by Dr. Butler to inaugurate the teaching of natural science at Harrow.

The task before the new-comer was by no means easy. The teaching of science, which had been forced on the attention of reluctant governing bodies by the recommendations of the Endowed Schools Commission, was regarded with scant favour by the majority of schoolmasters, while among the boys it was frankly disliked. At Harrow there was at that time neither laboratory nor special class-room; Griffith was allowed the use of a room when it was not being used by another master, but all apparatus had to be cleared away after each lecture before the entrance of the legitimate tenant. This state of things continued until about 1874, when properly equipped laboratories were erected. For twenty-six years (1867–93) Griffith taught at Harrow, in his earlier years taking physics, chemistry, geology and biology, according to the demand; latterly he confined himself almost exclusively to physics. In 1871 he entered into possession of a "Small House" (a boarding-house for nine boys), which he held until, in 1887, he succeeded Mr. Holmes as the master of "Druries," a larger and more responsible charge. In 1893 he retired from his mastership, having already been appointed (in 1890) assistant general secretary to the British Association for the second time.

His active connection with the British Association began at a much earlier date. We find him acting as local secretary at the Oxford meeting of 1860, memorable for the Huxley-Wilberforce battle over Darwin's works, while in 1862 he entered on his first term of office as assistant general secretary. Having resigned in 1878, he was prevailed upon to take charge of the work for the year 1881, during a temporary vacancy. In 1890 he was re-appointed, and carried on the work of his office with full vigour until an hour before his death.

During his latter years he threw himself with characteristic energy into the Royal Society's scheme for an international catalogue of scientific literature, a task for which he was singularly well fitted by wide learning, both scientific and linguistic, his unfailing memory and his fastidious accuracy of thought and expression.

He was laid to rest, on May 13, in the old churchyard of Harrow-on-the-Hill, above the little town that had been his home for thirty-five years, and the old school into which he had been the first to introduce the systematic teaching of science. B. P. L.

NOTES.

M. T. MOUREAUX, who has for twenty years been connected with the magnetic work of the Parc Saint-Maur Observatory, has been appointed to succeed the late M. Renou as director of the Observatory.

PROF. T. C. CHAMBERLIN, of Chicago, Dr. T. Thoroddsen, of Reykjavik (Iceland), and Prof. S. W. Williston, of the University of Kansas, have been elected foreign correspondents of the Geological Society.

THE Prince of Wales has consented to become an honorary member of the Linnean Society. The following gentlemen have been elected foreign members of the Society:—MM. A. Giard, H. J. Hansen, C. S. Sargent, F. E. Schulze and J. Wiesner.

ON Tuesday next, May 20, Prof. Karl Pearson will deliver the first of three lectures at the Royal Institution on "The Laws of Heredity, with Special Reference to Man." The Friday evening discourse on May 30 will be delivered by Mr. G. Marconi, on "Electric Space Telegraphy," and that on June 6 by Sir Benjamin Baker, on "The Nile Reservoirs and Dams.'

THE new botanical laboratories, presented to University College, Liverpool, by Mr. W. P. Hartley, were opened by Sir William Thiselton-Dyer, K.C.M.G., F.R.S., on Saturday last. The new Institute is an imposing building and the accommodation it affords will facilitate the advancement of the science of botany in Liverpool. The teaching of large classes of University students of botany is now not only possible, but easy; and in view of the probable early realisation of a University for Liverpool, this is a matter of some importance. Not only does Mr. Hartley's gift provide ample room for all probable increase in number of students, but the laboratories are equipped with the necessary appliances, both for elementary and advanced work. A special laboratory is set apart for investigations in plant physiology and another for anatomical research. The laboratories will thus not only become centres of teaching, but of work carried on with the view of contributing knowledge which will assist the progress of botanical science. We hope to give a description of the new Institute in a later issue.

LIVERPOOL has often given evidence of its appreciation of the men of light and leading whose activities bring honour to the city. The return of Prof. Herdman from Ceylon, where he has recently spent several months in the investigation of the Pearl Oyster Fisheries, on behalf of the Government, provided Liverpool biologists and others with an opportunity of expressing their esteem for his work. A large company, including the Lord Mayor and Lady Mayoress, assembled at a complimentary dinner given to Prof. and Mrs. Herdman last week under the auspices of the Liverpool Biological Society. In responding to the toast proposed by Sir William M. Banks, Prof. Herdman was prevented from speaking on the principal object of the expedition, namely, his work on the pearl oyster, because the Government report had not been presented, but he gave an interesting account of other sections of his work and of visits to places of interest in and about Ceylon.

THE annual conversazione of the Society of Arts will be held on June 24 at the Royal Botanic Gardens, Regent's Park.

A MEETING of delegates representing a number of natural history and photographic societies was held at Croydon on Friday, May 9, Mr. W. W. Whitaker, F.R.S., being in the chair, to consider and set in motion a photographic survey of Surrey. It was resolved that a society be formed to be called "The Photographic Survey of Surrey," and that its object be to preserve a record in permanent photographs of buildings of

interest, antiquities, scenery, geology, natural history, anthropology, and of portraits of notable persons, representations of passing events of local or historical importance, and of old records, rare books, prints, maps, so as to give a comprehensive survey of what is valuable and representative in the county of Surrey.

IN the death of Mr. John Clavell Mansel-Pleydell, of Whatcombe, near Blandford, Dorsetshire loses a man of wide influence and learning, a naturalist of the old school, distinguished for his labours on the botany, zoology and geology of his native county, and one who as magistrate and councillor had rendered great local services. He was born in 1817, educated at St. John's College, Cambridge, and succeeded to the family estates on the death of his father in 1863. He was a fellow of the Linnean and Geological societies, and one of the founders of the Dorset Natural History and Antiquarian Field Club, to the *Proceedings* of which he contributed many articles. He was author also of separate works on the flora, the mollusca and the birds of Dorsetshire. He died on May 3, 1902, aged eighty-four.

MR. J. MACFARLANE, honorary secretary of the Asiatic Society of Bengal, informs us that Sir Frank Athelstane Swettenham, K.C.M.G., the Governor of the Straits Settlements, has made the Society a grant of 2800 dollars, or Rs. 8750, for the purpose of completing the publication of the "Materials for a Flora of the Malayan Peninsula," by Sir George King, K.C.I.E., formerly superintendent of the Botanic Garden near Calcutta. The series of papers bearing this title is really a monograph, modelled on the lines of Hooker's well-known "Flora of India," of the flowering plants of the Malay Peninsula and the adjacent smaller islands, and it is as useful to the student as it is to the systematic botanist. The series was commenced in the *Journal of the Asiatic Society* for 1899, and up to last year nearly 1400 pages, including fifty-two natural orders, or rather more than half the work, had been published. One order, Leguminosæ, has been contributed by Major Prain, and Dr. O. Stapf, of Kew, has collaborated in the preparation of the suborder Melastomeæ. The Society's financial position would, however, scarcely permit the publication of the Malayan flora without support. At this juncture the Government of the Straits Settlements, which was naturally interested in the completion of the work, held out the prospects of financial aid being afforded, and has now sanctioned the liberal donation of Rs. 8750. This assistance places the Society in a position to complete without delay the publication of Sir George King's important contribution to the advancement of botanical research.

DURING a trial of M. Severo's air-ship at Vaugirard on Monday, an explosion occurred, causing the total destruction of the balloon and the death of M. Severo and his assistant, who were thrown to the ground from a height of more than one thousand feet. It is not known whether the accident was caused by an escape from the motors setting fire to the hydrogen in the balloon, or whether part of the machinery became heated and ignited the envelope, but the former appears to be the more probable cause of the calamity. The balloon shot up suddenly when it was released, and the expansion which must have occurred on account of the diminished pressure seems to have caused an escape of gas, which becoming ignited, resulted in the explosion. As the petroleum motor was little more than a metre from the envelope of the balloon, there was great danger that an accident of this kind would occur. In M. Santos Dumont's airship the motor was sixteen or eighteen metres from the balloon and far to the rear, so that the possible chance of gas ignition was much less. M. Severo designed his balloon with the object of avoiding the danger of pitching to which M. Santos Dumont's machine was liable. This feature must necessarily exist in the greatest degree in a machine in which the screw propellers are so placed that their resultant thrust has a considerable moment about the centre of the balloon. If the thrust acts nearly along the axis of the balloon and the car of the balloon is as close up to the balloon as possible, the pitching may be expected to be small. This was the essential feature of the Severo airship. The propulsion was effected by two screws attached to the balloon itself, and placed at either end of an axis that bisected the balloon longitudinally from end to end, while the car was drawn up close to the balloon. Another feature was the method of securing rigidity by means of a light rod running through the balloon from end to end and preventing it from crumpling in even if it should become somewhat deflated.

IN a letter to the *Times*, Earl Grey has directed attention to the important influence which the United States Fish Commission claim to have exerted upon the fish supply of their western coasts by means of the fish-hatching operations carried out by the Commission. The new illustration cited by the acting commissioner in his letter to Earl Grey has reference to salmon. It is stated that, of one lot of 5000 fingerlings released at the Clackamas (Oregon) hatchery in 1896, after having the adipose dorsal fin removed with a razor, 375 fish, averaging 27·7 lb., were captured in 1898 in the Columbia River basin and five in the Sacramento River (California); in the following year between forty and fifty others were taken, and in 1900 a number of others were reported, the fish caught in 1899 averaging 10 lb. heavier than those in 1898. It appears that not less than 450 marked fish, with an aggregate minimum weight of 10,000 lb., were secured in the second, third and fourth years following their release. "The foregoing figures mean that for every 1000 fingerling salmon liberated by this Commission on the Columbia River, 2000 lb. of adult fish were caught for market two to four years later. Reducing this to a financial basis, it appears that the cost of producing and planting young salmon is under 1 dollar per 1000 (including compensation of permanent employés), while the minimum value of the fish caught for market is 5 c. per pound, or 100 dollars for the 2000 lb. actually taken." The acting commissioner adds that it is the intention "to verify these results by additional and more conclusive marking experiments, which are already under way," and concludes his letter with a reference to the Commission's well-known success in introducing the Atlantic shad and striped bass into the waters of their west coast, where these fish now yield profitable fisheries. Everyone recognises the zeal and enterprise which the Americans have shown in the matter of fish-culture, as well as the success of their acclimatisation experiments cited above; and there will be general satisfaction, even among the Commission's critics, if they should ultimately be in a position to prove the commercial utility of their extensive salmon-hatching operations. The moral, however, which Earl Grey deduces for the behoof of our Fisheries Department, *i.e.* to go and do likewise, is more questionable. There is scarcely any need to introduce good fish into any of our British waters, and there are many who think that the salmon has already monopolised too much of the attention of our administrative authorities. On the other hand, a Fish Commission for Great Britain, on which science and practice were fitly represented, and which was provided with adequate means both for investigations and practical experiments, would fulfil a serious deficiency in our industrial organisation.

IN a small pamphlet of 21 pages which we have received, Father J. Fényi, S.J., describes a most ingenious apparatus for registering thunderstorms. The instrument seems to be due chiefly to the ingenuity of Father Johann Schreiber, S.J., an assistant a the Haynald Observatory in Kalocsa, who constructed it. The

apparatus consists mainly of three portions; the first consists of a horizontal magnetic needle mounted on a vertical support between a small and sensitive coil of wire, the needle and its stop being connected with a battery, a bell and a registering apparatus, the needle when in contact with its stop completing the circuit. The registering apparatus is a small electromagnet which actuates a pen in contact with a disc, and the latter is connected with a clock and moves with regular velocity. The third and very important portion of the arrangement is the coherer, which is composed of two delicately suspended needles nearly in contact; these are connected in a circuit, which includes the coil in which the horizontal needle is placed, a cell, and the long intercepting wire, corresponding to the tall post with wire of the Marconi telegraph system. The apparatus works in the following manner. A distant flash of lightning starts a wave-impulse, and this is led to the coherer by the intercepting wire; the needles move and touch each other, thus completing the circuit, and allow a current to pass through the coil. This coil immediately causes the needle inside it to be deflected to the stop. The second circuit is thus completed, the needle on the registering apparatus marks a deflection on the disc, the bell is rung, and the vibration caused by the latter separates the needles of the coherer. According to the account here given, the instrument is very efficient and has been found to record storms as many as twenty miles away, while on another occasion the instrument during very fine weather was working "apparently rebelliously," but was really recording a great storm raging at Budapest (as shown by the time of occurrence and record at each place), a distance of 110 kilometres from the apparatus.

IN the *Scientific Transactions* of the Royal Dublin Society for April, Prof. F. T. Trouton discusses the remarkable experiment suggested by the late Prof. Fitzgerald for testing the relative motion of the earth and the æther. The idea of the experiment is that a charged electrical condenser, when moving through the æther with its plates edgeways to the direction of motion, possesses a magnetic field between the plates in consequence of its motion in accordance with the generally held view that a moving charge is equal to an electric current. As Prof. Trouton points out in the second part, the experimental realisation of the results anticipated opens up the possibility of utilising the earth's energy of motion through space, but it appears, so far as the observations go, that the effects sought are masked by some countervailing phenomena. In examining the paper at the present time, the recent discussions of Cremieu, Righi and other physicists on the question whether moving charges do actually generate a magnetic field, and allied points in the theory of electromagnetism, must not be overlooked.

WE have received a copy of a paper, by Mr. R. S. Hutton, on the fusion of quartz in the electric furnace. Mr. Hutton found that quartz can be readily fused in a Moissan arc furnace taking 300 amperes at 50 volts, and if air is supplied during the process reduction can be prevented. A modified form of furnace was built with a trough cut at right angles to the carbons, so that a carbon mould filled with broken-up quartz can be pushed under the arc. For making tubes, a carbon core is used, which is easily withdrawn afterwards, as it does not stick to the quartz. The tubes thus prepared are not quite free from bubbles, but can be improved in appearance by reheating under the arc, and, being thick-walled, can be used for drawing down and blowing. Mr. Hutton expresses the hope that this process may be extended by those having large supplies of power at their disposal, and may prove cheaper and more easily worked than the present method of fusion in the oxyhydrogen flame. Fused quartz apparatus might then be easily available, and its valuable properties would ensure its use for many purposes. Chief among these may be noted its low coefficient of expansion, its high melting point, and its power of withstanding sudden changes of temperature without cracking.

THE last number of the *Journal* of the Russian Physical and Chemical Society (vol. xxxiv. 2) contains a paper by Prof. Bohuslav Brauner on the position of the rare earths in Mendeléeff's periodical system of elements, which led to a very interesting discussion when it was read at the last Congress of Russian Naturalists. After having mentioned his experimental and theoretical work concerning the elements lanthanum, cerium, praseodymium, neodymium, thorium, &c., the author discussed the position of these elements in the periodic system, and the four different ways in which it may be attempted to place them in it. With Mr. Steele, of Melbourne, he comes to the conclusion that this group of elements represents a sort of node in the periodic system, between cerium and an unknown element which has the atomic weight of 180. This inter-periodic group is a continuation of the eighth series, which ends with the platinum elements; gold appears in such case as the first member of the ninth series, and not of the eleventh. In the twelfth series the first members are, probably, radium, thorium and uranium. This addition seems, in Mendeléeff's opinion, to deserve serious attention.

IN the latest *Bollettino* of the Italian Seismological Society, Dr. Cancani reconsiders the periodicity of the great earthquakes which have visited the coasts of the Marches and Romagna. By the discovery of some missing records, he has been able to fill up two gaps in the series, which now extends from 268 B.C. to 1874 A.D. The intervals between successive great earthquakes vary from 93 to 114½ years, the average interval being 101·9 years.

SOON after the Riviera earthquake of February 23, 1887, the geodynamic section of the Central Meteorological Office of Rome commenced the systematic record of all Italian earthquakes. During the first three or four years, the new section was getting into working order, but from 1891 onwards it attained that uniformity and regularity which now characterise it. The results of the first ten-year period (1891–1900) are summarised by Dr. A. Cancani in a paper published in the last *Bollettino* (vol. vii. No. 6) of the Italian Seismological Society. Taking into account only those shocks that were perceptible without instrumental aid, he finds that no less than 3361 earthquakes were observed in Italy during the ten years. The maximum monthly numbers occur in July and August, but this distribution is accidental and due to the very numerous shocks which followed the Monte Saraceno (Foggia) earthquake in July and August, 1893. During the last five years, the maximum numbers are found in January and March. The hourly distribution of earthquakes shows a minimum between 5 and 8 p.m. and a maximum in the first hour after midnight. Seismologists usually consider the midnight maximum as apparent and due to the condition of the observers, but Dr. Cancani remarks that the ratio of night earthquakes to day earthquakes is the same, namely 1·5, both for weak shocks (of intensities 2 to 4) and for strong ones (intensities 5 to 8). This is in direct contradiction to results previously obtained by de Montessus.

DR. HERGESELL, president of the International Aeronautical Committee, has communicated the following preliminary results of the balloon ascents which took place on the morning of February 6:—Strassburg, (1) temperature on ground $-0°·9$ C., $-39°·7$ at 8290 metres; (2) temperature at starting $-0°·1$, $-6°·8$ at 3600 metres. Berlin, temperature $-4°·4$, and $-12°·9$ at 3635 metres. Vienna, (1) temperature $-8°·6$, and $-12°·0$ at 3760 metres; (2) with Archduke Leopold Salvator and Archduchess Blanca in the car, temperature $-9°·0$ at 3000 metres

(temperature at starting not stated). Ascents were also made at Trappes (Paris) and Pavlovsk (St. Petersburg), but the results are not yet known. Mr. Rotch sent up a kite from Blue Hill Observatory, U.S. The lowest temperature, corresponding to the time of the European ascents, was −16°·0 at a height of 1242 metres. During the period in question there was an area of low barometric pressure over western Europe, which extended from Spain to Scandinavia, while over the eastern part of the continent there was an area of high pressure; the ascents from Vienna were made under the influence of the latter atmospheric conditions.

RESEARCHES carried on by Prof. F. E. Weiss on a Carboniferous plant-remain found at Halifax, and named *Xenophyton radiculosum* by Mr. Thomas Hick, show that the specimen may with little hesitation be regarded as the "root" of *Lepidophloios fuliginosus*—a view which supports the contention of the late Prof. W. C. Williamson that the plant was of stigmarian character. (*Manchester Memoirs*, vol. xlvi., 1902, No 9.)

THE *Annuaire* of the Royal Academy of Belgium for 1902 contains a biography, with portrait, of the late Baron de Selys Longchamps, who died at Liege in 1900. It appears that the family of Selys has been intimately connected with Liege since the seventeenth century. Full justice is done in the memoir to his work on the natural history of his own country, as well as to that on ornithology, ichthyology, and other branches of biology in general.

THE movements of gregarines are discussed by Mr. H. Crawley in the first part of the *Proceedings* of the Philadelphia Academy for 1902. The theory that these tiny organisms possess a kind of passive locomotion by means of the gelatinous threads they exude from the hinder part of the body is rejected—for one reason because such a mode of motion is unparalleled in the animal kingdom. Instead of this, the author believes that locomotion is effected by transverse muscular movements in the body, although the exact nature of the action and its results can only be surmised.

IN the *Proceedings* of the U.S. Museum (vol. xxiv.), Mr. Jordan, assisted in one case by Mr. M. Sindo and in another by Mr. J. O. Snyder, continues his valuable illustrated review of the fishes of Japan. Four parts are now before us, the first dealing with the surf-fishes (Embiotocidæ), the second with the angler-fishes, the third with the "trachinoids," and the fourth with the salmonoids. With regard to the lack of sharply defined specific or subspecific characters between the numerous forms of the latter, the authors are inclined to adopt the view that this is in part at least due to the modern origin of the group.

PROF. H. F. OSBORN, in the April number of the *American Naturalist*, urges the importance of "homoplasmy" as a law of latent or potential homology, taking for his text the independent origin of certain cusps in the cheek-teeth of the Primates which are clearly homologous. Assuming that all teeth started from the tritubercular type, we are forced to the conclusion that there is some principle in the constitution of these teeth which unifies up to a certain point the subsequent variation and evolution.

AN explanation of the survival of the brachiopod genus Lingula from Cambrian times is offered by Mr. N. Yatsu in *Annotationes Zoologicae Japonensis* (vol. iv. part ii.). A part of the Japanese coast where this brachiopod flourishes was a few seasons ago coated with a deposit of muddy sediment from a flooded brook. All the burrowing molluscs were immediately killed, but the Lingula were unharmed. As it is also known that Lingula will live in an aquarium after the water has become unfitted for other organisms, it is inferred that its survival is due to its power of withstanding unfavourable conditions. In the same journal, Mr. H. Kuwano describes a new Japanese Balanoglossus.

THE presidential address delivered by Dr. Erwin F. Smith before the Society for Plant Morphology and Physiology is published in full in a recent number of *Science*. Taking "Plant Pathology" as the subject of his discourse, comparisons are instituted between the conditions under which the pathologist worked twenty years ago and the improved modern-day methods. At that time pure cultures were almost unknown, and precise fixing and staining methods had not been devised. Then follows a considerable list of important researches from the time of De Bary down to the present day. Finally, looking forward, Dr. Smith suggests that the pathologist of the future will require to consult or, better still, train himself as a chemist and physicist. A preparation of eight years is considered to be none too long to fit the future pathologist for his life's work.

WE have received a copy of a syllabus of a special course in natural history for training college and King's students, issued, under the supervision of Prof. J. A. Thomson, by Marischal College, University of Aberdeen, for their summer session. The book, which is beautifully illustrated, appears in every way admirably adapted to the purpose for which it is intended. It commences with an examination of a series of types of British vertebrates, followed by a selection of invertebrates. Then comes a discussion of the principles of classification, with brief definitions of varieties, species, genera, &c. The structure of the cockroach is then exemplified, after which we have a brief table of the animal kingdom with appropriate illustrations. Another lesson deals with living animals, this being followed by a discussion on adaptation to surroundings and mode of life. The pupil is then introduced to the leading features in the structure of limbs, after which development claims his attention. Finally, there are illustrated studies of various types of common animals from four different points of view.

THE first number of the fortnightly *Agricultural News* (16 pages, one penny) was published by the Imperial Department of Agriculture for the West Indies on April 25, and has been very well received by the colonials. Its contents are of a most varied character, appealing to all classes of cultivators in the islands, dealing, not only with the staple industry, sugar, but also with bats, beetles, tarpon fishing, grape cultivation, market reports, notices of books, &c. It is proposed to make a special feature of reports on the work which is being carried on at chemical laboratories, botanic institutions, agricultural shows, &c., and of the promotion of agricultural education in the colleges and schools of the West Indies. In future the *West Indian Bulletin* will be the quarterly journal of the Department for scientific and technical readers, while the *Agricultural News* will be the publication for the masses and the classes. Although the Department has only been in existence a little more than three years, it is evidently already widely appreciated, for its publications have now an extensive circulation in all parts of the tropics, the income from the sales disclosing a steady increase.

DR. HERBERT J. WEBBER has published a complete account of his investigations on the germination of the pollen grain and the series of events leading to fertilisation in two species of Zamia (U.S. Department of Agriculture, Bureau of Plant Industry, *Bull.* 2, 1901). The paper is a valuable addition to our knowledge of a most important race of plants, and the author's treatment is critical as well as descriptive. He shows that the male prothallium consists at first of two (or possibly three) cells, of which the terminal one divides into a stalk and "central" cell (the latter = antheridial cell of other authors). From the central cell the two antherozoids are formed, and the entire mass is used in their formation. The blepharoplasts,

which ultimately serve as the starting place for the coil of cilia in each antherozoid, are regarded as organs *sui generis;* and although their possible relation to centrosomes is also considered, the arguments against their identity with the latter are cogent. In fertilisation, the entire antherozoid enters the egg, and the cytoplasm and nuclei of the male and female cells respectively become fused. No centrosomes were observed during the cleavage of the fertilised egg during the formation of the embryo.

WE have received from the publishers (Messrs. Cassell, Ltd.) a copy of the first part of an illustrated quarto work on "European Butterflies and Moths," by Mr. W. F. Kirby, the well-known lepidopterist. The plates are excellent examples of modern colour-printing, and the work, so far as it has yet gone, may be described as an attractive subject attractively treated. Perhaps it would have been better if a little more prominence had been given in the text to the English names. The work is to be issued in fortnightly parts.

A VOLUME containing the physical papers of the late Prof. H. A. Rowland is now in preparation. It will be issued under the editorial direction of a committee appointed for that purpose, consisting of President Remsen, Prof. Welch and Prof. Ames. The book will contain Prof. Rowland's articles and memoirs on physical subjects, together with his popular writings and addresses, numbering sixty in all. It will occupy between six and seven hundred pages, and will be published at the price of one guinea net per copy. Orders may be sent to Prof. Joseph S. Ames, secretary of the committee of publication, Johns Hopkins University, Baltimore, Maryland.

THE industry of chemical perfumes is one of recent development and is rapidly assuming an importance second only to the colour industry in the field of commercial organic chemistry. The current number of the *Moniteur Scientifique* contains an account by MM. Marc Tiffenau, R. Bernard and A. Gloess of the exhibits in this field at the Paris Exhibition of 1900, preceded by a short sketch of the general methods employed in the preparation of chemical perfumes. It is interesting to note that practically the whole of this branch of applied science is divided between two nations, France and Germany.

THE conclusion of Maxwell from the electromagnetic theory of light that the dielectric capacity should be equal to the square of the refractive index has led to a mass of experimental work not always in accord with the law. In the current number of the *Comptes rendus*, M. Edm. van Aubel collects the experimental data for these two constants for four classes of nitrogen compounds, amines, alkyl nitrates, fatty nitro-derivatives and nitriles, and shows that in all cases the dielectric constant diminishes as the molecular weight increases, whilst the refractive index increases, a result obviously incompatible with Maxwell's law.

THE additions to the Zoological Society's Gardens during the past week include two Lesser Kestrels (*Tinnunculus cenchris*), a Short-eared Owl (*Asio brachyotus*) captured in the Red Sea, presented by Capt. E. W. Burnett; a Red-footed Falcon (*Tinnunculus vespertinus*), South European, presented by Miss E. Leeke; a Virginian Eagle Owl (*Bubo virginianus*) from the West Indies, presented by Mr. B. C. Storey; a Common Mynah (*Acridotheres tristis*) from India, presented by Mr. F. G. Miéville; two Syrian Bears (*Ursus syriacus*) from Western Asia, twenty-two Moorish Toads (*Bufo mauritanica*) from North-west Africa, five Amphiumas (*Amphiuma means*), ten Punctated Newts (*Amblystoma punctatum*) from North America, an Upland Goose (*Chloephaga magellanica*) from the Falkland Islands, received in exchange; a Japanese Deer (*Cervus sika*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

NEW VARIABLE STARS.—The following variable stars have been detected on plates taken with the astrographic telescope at Greenwich Observatory :—

Star.	R.A.	Decl.	Variation.
	h. m. s.	° ′	m. m.
6. 1902. Draconis	... 18 5 9 ...	+65 56·9 ...	9·0 – <14
7. 1902. Draconis	... 18 6 54 ...	+66 8·9 ...	9·5 – 14
8. 1902. Camelopardalis	5 49 22 ...	+74 30·8 ...	8·9 – <14

ELEMENTS OF COMET 1902 *a* (BROOKS).—The following elements computed for this comet are given in *Astronomische Nachrichten*, Bd. 158, No. 3790 :—

T = 1902 May 7·159, Berlin M.T.

$$\left.\begin{aligned} \omega &= 228^\circ\ 22'\cdot7 \\ \Omega &= 52\ \ 15\cdot4 \\ i &= 66\ \ 30\cdot4 \end{aligned}\right\} 1902\cdot0.$$

$$\log q = 9\cdot65436.$$

COLABA OBSERVATORY.—The Report of the Director of the Government Observatory at Colaba, Bombay, has been issued, and contains the results of magnetic and meteorological observations made during the year 1901.

The magnetic observations have been on regular record since 1842, but there is now reason to believe that disturbances will occur from the proximity of the electric tramways in Bombay. It is hoped, however, that a new site will be granted early enough to permit of a fresh series of determinations running parallel with the present, so that the value of such a long continuous record may not be seriously affected.

ATOMS AND VALENCIES.

AN offprint has come to hand of a thoughtful essay by Mr. J. Fraser, of the Scottish Ordnance Survey, entitled "A Theoretical Representation leading to Suggestions bearing on the Ultimate Constitution of Matter and Ether," which appeared recently in *Proc.* Roy. Soc. Edin. xxiv., i., 1902, pp. 1–64. Under this guarded title the writer discourses, in a manner often stimulating and suggestive, on the bearing on the facts of chemistry and chemical physics of a notion he has formed of the constitution of the æther, and of matter which he considers as constructed out of that medium. He begins by quoting Sir J. Herschel's opinion that the æther is "an adamantine solid," far denser, in fact, than the densest metal. The other alternative, that of inertia or density insensibly minute, has been more commonly in evidence in recent times, especially since Lord Kelvin showed that it was adequate for the transmission of radiant energy across space. It is something to know that the more unfamiliar view, which has recently again been broached in illustration of the laws of general æther-theory, presented no intrinsic difficulty to the mind of so competent an authority as Herschel. Enormous density implies still more enormous elastic resistance, which Mr. Fraser ascribes in a way to a kinetic origin, like Kelvin's and FitzGerald's turbulent motion. How is an atom of matter to be represented? Briefly and bluntly, in the words of the writer, as "a veritable ethereal bubble"—walled in by a single layer of æther-particles, in very rapid rotation, the centrifugal force of which prevents the bubble from collapsing under the enormous ambient pressure. How is its permanence assured? Astronomical analogies are invoked in favour of its possibility; but the sceptical critic had better refrain from too close scrutiny in order to pass on to see whether any light on atomic behaviour is shed by a somewhat loose representation of this sort. After all, a hollow vortex-ring atom is a ring-shaped bubble kept open much in this way; and representations dynamically vaguer than this have turned out in chemical science to contain the germ of fruitful and far-reaching progress. A sort of Le Sage corpuscular theory of gravity is set forth with considerable freshness and some plausibility. But the most interesting sections relate to chemical suggestion, with regard to which the writer modestly confesses to little knowledge except what has been acquired with a view to the present attempt. It may be remarked on his behalf that knowledge of speculative scientific theory, when acquired with some constructive intention of this sort, even if it be visionary, is apt to be a much more real possession than when the aim is merely to become well-informed in a colourless way about the opinions that

chemists have held and have at different times put into their treatises. Time and reflection, to an extent that can hardly be spared by most people, would be required to come to a definite judgment as to how far the notions put forward are allowable or should be at once put aside, whether the "resemblance to the ways of nature" on which the writer insists involves any germ of general ideas beyond those already recognised. But in any case there can be no question as to the acuteness of the writer; and the Royal Society of Edinburgh has been well advised in making his ideas accessible to others who are attracted by the same range of theoretical speculation, in subjects which are only now coming to the threshold of the dynamical stage.

J. L.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The subject of the Rede lecture, to be given by Prof. Osborne Reynolds, F.R.S., on June 10, at 11.30 a.m., is "On an Inversion of Ideas as to the Structure of the Universe."

Prof. Forsyth, F.R.S., will represent the University at the celebration of Abel's centenary, to be held at Christiania in September, 1902.

The museums syndicate propose to assign the greater portion of the buildings about to be vacated by the botanical department to the engineering laboratory. The number of the students engaged in the latter is now more than 200, and extension of the accommodation now provided is urgently necessary. The syndicate regret that they are unable to make arrangements for additional accommodation for the departments of human anatomy and physiology, or for the museum of zoology, which are also in need of considerable expansion.

The Graces authorising the recently proposed changes in the natural sciences tripos will be voted on in the senate on May 22. It is understood that some of them will be opposed.

Mr. W. Bateson, F.R.S., is again to be deputed to lecture in zoology for Prof. Newton during the ensuing academical year.

The Frank Smart studentship in botany will be vacant at midsummer. The studentship is of the annual value of 100*l.* and is intended to further the scientific study of botany by supplying students with some means of pursuing original investigations in this subject after they have taken the degree of Bachelor of Arts. It is open to all students of the University who have taken honours in the first part of the natural sciences tripos, provided that not more than fourteen terms have elapsed since their first term of residence. The studentship is not awarded by a competitive examination. Candidates should send in their names to the master of Gonville and Caius College on or before June 10, with a statement of their University standing.

THE second reading of the Education Bill was passed by the House of Commons on Thursday, May 8, after a debate which extended over three days. The majority in favour of the second reading was 237, the numbers being 402 votes for the Bill and 165 against.

To assist the scholarship scheme founded by the late Mr. Rhodes, Sir Alfred Jones, head of the shipping firm of Elder, Dempster and Co., announces that he will agree to give a free passage backwards and forwards from any colonial port served by his firm's steamers to both Jamaican and Canadian scholars once a year during the tenure of their scholarships. He adds:—"I trust that my example will be followed by shipowners trading to other colonies, and I hope that it may thereby be made universal, so as to put all the Rhodes scholarships from the colonies on an equal footing."

THE announcement is made that Prof. Karl B. Lehmann, of Würzburg, has been appointed to the chair of hygiene at the University of Munich, which recently became vacant by the death of Prof. Hans Buchner on March 30. He was formerly connected with the University, having been trained there as a medical student, and subsequently acted as assistant to Prof. Pettenkofer and as privat-docent for many years. Prof. Lehmann, who is a Swiss by birth, is still in the prime of life, but has already made a high reputation as a hygienist. His first special scientific work was the study of the physiology of the sense-organs, his contributions to this department of science being of great and practical value. He has also studied and written upon the action and influence of various gases upon the animal organism, and more recently has given much attention to the study of physiological chemistry in connection with general metabolic processes.

IN connection with the subject of State aid for secondary education, it is of interest to read in *Science* that the General Assembly of the State of Iowa has passed a mill tax for the building support of the three educational institutions of Iowa, as follows:—State University at Iowa City, one-fifth of a mill to run for five years. This will realise 550,000 dollars. The Iowa State College of Agriculture and Mechanic Arts at Ames, one-fifth of a mill for a similar period, which will realise 550,000 dollars. The State Normal School at Cedar Falls, one-tenth of a mill for five years, which will realise 225,000 dollars. The State educational institutions receive in addition 434,269 dollars for the biennial period, distributed as follows:—State University, 215,000 dollars; Iowa State College of Agriculture and Mechanic Arts, 135,000 dollars—of this 35,000 dollars are for additional general support annually, and 10,000 dollars annually for the experiment station, 5,000 dollars for live stock, 5,000 dollars to begin the building of a barn, and 35,000 dollars to start a main central building; the Iowa State Normal School, 84,269 dollars.

THE general scope of the new matriculation examination for all students of the University of London are published in the official gazette. The full text of the regulations will be published at the beginning of June, and the first examination under them will commence on September 15 next. An examination under the old regulations will be held in January, 1903, and under both sets of regulations in June, 1903. Matriculation candidates will be expected to show a competent knowledge in each of the following subjects, according to the details specified under the several heads:—(1) English, one paper of three hours. (2) Elementary mathematics, two papers of three hours each. (3) Latin, or elementary mechanics, or elementary physics (heat, light and sound), or elementary chemistry, or elementary botany, one paper of three hours in each subject. (4) Two of the following subjects, neither of which has already been taken under (3). One paper of three hours in each subject. If Latin be not taken, one of the other subjects selected must be another language from the list, either ancient or modern:—Latin, Greek, French, German, Arabic, Sanskrit, Spanish, Portuguese, Italian, Hebrew, history (ancient or modern), logic, physical and general geography, geometrical and mechanical drawing, mathematics (more advanced), elementary mechanics, elementary chemistry, elementary physics—(*a*) heat, light and sound, or (*b*) electricity and magnetism; elementary biology—(*a*) botany, or (*b*) zoology.

DR. D. C. GILMAN contributes to the May number of *Scribner's Magazine* some further reminiscences of noteworthy scholars with whom he has been brought in contact as president of the Johns Hopkins University. An English mathematician remarked to him one day that he had heard of Baltimore as a place which exported corn and imported mathematics, and this epigram was founded upon fact. Cayley and Sylvester both went to the new University from England. Cayley spent a winter at Baltimore, and profoundly impressed his hearers; Sylvester spent the seven years there which preceded his seventieth birthday, and left to become Savilian professor at Oxford. Many stories are told of Sylvester's eccentricities, but most of them are apocryphal. He became possessed of a sort of monomania for rhyme, and one of his most extraordinary compositions was a long series of lines, every one of which ended with a syllable that he pronounced as *ind.* This *tour de force* reached four or five hundred verses. Sometimes he was very absent-minded. For example, he arrived from Philadelphia in a late train one night and walked bareheaded to his hotel. The next morning he demanded his hat, and insisted that it was in the house, and he would not be persuaded that it had not been stolen until a telegram revealed the fact that the hat had been found in the train at Washington. In 1884, Lord Kelvin gave a course of lectures at the University. "The lectures," says Dr. Gilman, "went on from day to day upon the topics that occurred to the lecturer, or that were suggested by the questions of his hearers. Everyone who was capable of following him was enchanted. 'How long will these lectures continue?' asked one of the audience. 'I do not know,' replied Lord Rayleigh, who was one of the

followers, 'I suppose they will end some time, but I confess I see no reason why they should.'" Dr. Gilman concludes his article with the following wise words:—"In the conduct of a university, secure the ablest men as professors, regardless of all other qualifications excepting those of personal merit and adaptation to the chairs that are to be filled. Borrow if you cannot enlist. Give them freedom, give them auxiliaries, give them liberal support. Encourage them to come before the world of science and of letters with their publications. Bright students, soon to be men of distinction, will be their loyal followers, and the world will sing a loud Amen."

SCIENTIFIC SERIAL.

Memoirs of the Kazan Society of Naturalists, vol. xxxv.—Researches into the Protozoa of the Black Sea, by R. Minkiewicz. The organisation, the multiplication and the systematical position of Euplotes (Ehrbg.) are discussed.—Materials for the knowledge of the soil and vegetation of western Siberia, by A. Gordyaghin. This is the second and last part of a very valuable work which was began in a previous issue of the same periodical (vol. xxxiv.). The fir, Scotch fir and birch forests, the mutual relations between the chief arborescent species, and the Steppe vegetation are discussed in this part, which contains also a large-scale botanical map of the western portion of the basin of the Irtysh and a full index.—The physicochemical structure of the chlorophyll grain, by M. S. Tsvett. Experimental researches and critical review of the work hitherto done.—Botanic-geographical researches in the province of Saratov, by B. Keller. An interesting general review of the vegetation (summary in German) and a list of 987 plants belonging to the flora of Saratov are given.—On the soils of south-eastern Russia, by A. Ostriakoff, being descriptions and chemical analyses of salt-bearing soils of southern Samara.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, May 9.—Prof. S. P. Thompson, president, in the chair.—Dr. P. E. Shaw exhibited a simple electric micrometer. Two years ago, Dr. Shaw described an instrument with which he measured very small lengths by the application of electric contacts, and the micrometer shown was a simple form of the original apparatus. A screw, fitted with a milled head, turns in a fixed nut, and its lower end presses upon the extremity of the long arm of a lever. A metal point is attached to the short arm, and the distance through which it moves, on turning the milled head, can be deduced from a knowledge of the pitch of the screw and the ratio between the arms of the lever. In using the instrument, this point is always brought up to a metal surface, and the contact is accurately determined by the telephonic arrangement described in connection with the original micrometer. Dr. Shaw illustrated the use of the instrument for measuring small lengths by describing the following eight applications to ordinary laboratory measurements:—(1) The measurement of the thickness of plates, films or fibres. The object is placed between two metal plates. The point of the micrometer is adjusted to touch the top plate and the reading taken. The object is removed, the point is again brought into contact with the top plate, and the difference between the readings in the two cases gives the thickness of the film. (2) The determination of Young's modulus by the elongation of a wire. Dr. Shaw described experiments on two wires, each $2\frac{1}{2}$ metres long, hanging side by side, one of copper and the other of steel. The wires terminated in horizontal platforms to which the stretching weights were attached. The base of the instrument rested on one platform, while depressions of the other, due to loading, were measured. In this way any error, on account of the bending of the beam from which the wires were hung, was eliminated. (3) The determination of Young's modulus by the bending of a beam. (4) The determination of simple rigidity by a static method. Observations were made upon a rod held horizontally by rigid wall brackets. One end of the rod was fixed and the other held in position by a pin pressed into a hole in the end of the rod. From this end an arm projected outwards. Weights were applied to the extremity of this arm, and the twist measured by observing with the micrometer the movement of the end of the arm. (5) Application to the extensometer. (6) Measurement of thermal expansion. (7) Microscopic measurements. In measuring the diameter of a capillary tube, the cross wire of the microscope is made to touch one side of the tube, and the point of the micrometer is brought into contact with the metal stage. The stage is then moved by a screw until the cross wire comes to the other side of the tube. The micrometer point is moved into contact again, and the difference in the readings gives the diameter of the tube. In this measurement the full magnifying power of the microscope is utilised, and the work of moving the stage is performed by a rough screw. (8) The direct measurement of the wave-length of light. Newton's rings are formed by a convex lens and a piece of plate glass. The convex lens is fixed to the short arm of the lever, and the distance through which it must be moved to cause a certain number of bands to appear at the centre gives a means of calculating the wave-length of the light employed.—Papers on the conservation of entropy, by Mr. J. A. Erskine, and rational units of electromagnetism, by Sig. G. Giorgi, were postponed.

Chemical Society, April 30.—Prof. Emerson Reynolds, V.P.R.S., in the chair.—The preparation of absolute alcohol from strong spirit, by Dr. Young, F.R.S. The 4 or 5 per cent. of water remaining in the strongest rectified spirit procurable by distillation can be removed by adding to it a volatile liquid capable of forming with alcohol and water a ternary mixture boiling below 78°·3 C. and distilling. Benzene is a suitable substance for this purpose, the ternary mixture so formed boiling at 64°.85. The alcohol thus obtained contains a trace of benzene, which in turn can be removed by a redistillation with pure hexane.—On the properties of mixtures of the lower alcohols with water, by Dr. Young, F.R.S., and Miss E. C. Fortey. Methyl alcohol can be prepared in an absolute condition by simple distillation through an efficient still-head. The higher homologues, such as isopropyl, propyl and tertiary butyl alcohols, can be dehydrated by addition of benzene and redistillation. The constant boiling mixtures of these alcohols with water are not definite hydrates.—On the properties of mixtures of the lower alcohols with benzene and with benzene and water, by Dr. Young, F.R.S., and Miss E. C. Fortey. Among the lower alcohols of the paraffinic series, all except isoamyl alcohol form constant boiling mixtures with benzene, but beyond the amyl alcohols this phenomenon no longer occurs; ethyl, propyl, isopropyl and tertiary butyl alcohols alone form constant boiling ternary compounds with benzene and water.—Fractional distillation as a method of quantitative analysis, by Dr. Young, F.R.S., and Miss E. C. Fortey. When a mixture which tends to separate into two components is distilled, the portion of the distillate obtained below the temperature midway between the boiling points of the two constituents is almost exactly equal to the weight of the more volatile component of the mixture. This principle can also be extended to ternary mixtures.—On the vapour pressures and boiling points of mixed liquids, by Dr. Young, F.R.S. Mixtures of bromo- and chloro-benzene exhibit a close agreement with van der Waals's law, which states that "the relation between vapour pressure and molecular composition of mixtures of liquids having equal critical points and in which $a_{1\cdot 2} = \sqrt{a_1\ a_2}$ (where $a_{1\cdot 2}$ represents attraction of unlike molecules and a_1 and a_2 the attractions of like molecules) is represented by a straight line."—The correction of the boiling points of liquids from observed to normal pressure, by Dr. Young, F.R.S. An extension and improvement of Craft's table of constants of correction.—Vapour pressures and specific volumes of isopropyl isobutyrate, by Dr. Young, F.R.S., and Miss E. C. Fortey. These constants have been determined on a pure specimen of this ester prepared by electrolysis of potassium isobutyrate.—The preparation of highly substituted nitroaminobenzenes, by Dr. Orton. The author has devised a method of preparing aromatic nitroamines by the action of nitric acid on amines dissolved in acetic anhydride, and has by this method isolated and characterised a number of these substances.—The atomic weight of tellurium, by Dr. Scott, F.R.S. When tellurium is treated with methyl iodide, it forms a trimethyl tellurium iodide which crystallises well and affords a convenient method of comparing the combining weight of tellurium with that of iodine which is accurately known from Stas's determination. The ratio thus found indicates that the atomic weight of tellurium is about 127·75.—Nitrogen bromides containing the propionyl group, by Dr. Chattaway. A

continuation of the author's researches on nitrogen halides in which propionyl is a substituent. A number of these derivatives are described.

Mathematical Society, May 8.—Dr. E. W. Hobson, president, in the chair.—Dr. Ganesh Prasad read a paper on the use of Fourier's series in the theory of conduction of heat. It is pointed out that the received theory may break down through discontinuity in the initial conditions; and a method is described for forming an equation which shall, at the discontinuities, take the place of the usual partial differential equation of conduction. The modified theory thus deduced is equivalent to the ordinary theory at all places and times at which there is no discontinuity in initial or boundary conditions.—Mr. A. E. Western pointed out an exception to a theorem of Fermat's on binary powers.—Dr. F. S. Macaulay read a paper on some formulæ of elimination. The resultant of any number of equations, which are homogeneous in an equal number of variables, is proved to be expressible as the quotient of a certain determinant by a certain minor of the same; certain formulæ are also given connecting the determinants with the roots of the equations which, for this purpose, are made non-homogeneous by equating one variable to unity.—The following papers were communicated from the chair.—Prof. Burnside, on groups in which every two conjugate operations are permutable. The general character of the operations of a group which satisfy this condition of permutability is determined, and it is shown that the sufficient and necessary conditions that the group may be of finite order are that the generating operations are of finite order. In general for such a group, the commutator of any two operations is a self-conjugate operation. The case in which the order is a power of three is exceptional.—Mr. H. S. Carslaw, the application of contour integration to the solution of general problems in the conduction of heat and to the expansion of an arbitrary function in series. The solutions of certain special problems are transformed so that they are expressed in terms of integrals taken along certain paths in the plane of an auxiliary complex variable. The solutions of more general problems, built up by synthesis, are then transformed so that they are expressed by means of infinite series. The methods are applied to problems of conduction of heat in a finite rod and in a cylinder, and it is pointed out that they admit of extension to other branches of mathematical physics.

Geological Society, April 16.—Prof. Charles Lapworth, F.R.S., president, in the chair.—The Carlisle Earthquakes of July 9 and 11, 1901, by Dr. C. Davison. The shocks were at least four in number, and there are single records of four other shocks. The isoseismal 5 of the first and principal shock is very nearly a circle 29 miles in diameter, with its centre 7 miles south-south-west of Carlisle, and is excentric with regard to the isoseismal 4. The continuity of the shock over a band extending from Carlisle to Coniston implies a corresponding continuity in the focus. The investigation of the earthquakes has led to the recognition of a deep-seated fault, the average direction of which is N. 5° E. and S. 5° W. and the hade throughout is to the east. In the surface-rocks there is no sign whatever of such a structure. The movements along the fault were somewhat peculiar. In the first shock the focus was of considerable length, and consisted of two principal portions, the centres of which were about 23 miles apart, connected by a region wherein the slipping was continuous throughout, and much less in amount. The northern part of the focus was smaller than the other, but was marked by a much stronger impulse. The third slip was complementary to the first, for it appears to have occupied the whole of the region between the two principal portions of the first focus, and to have been greatest near the centre of that region and to have gradually diminished towards both ends.—The Inverness Earthquake of September 18, 1901, and its accessory shocks, by Dr. C. Davison. Since the Comrie earthquake of 1839, which was followed by 330 tremors and earth-sounds within little more than two years, no British earthquake has been attended by so many accessory shocks as this one. The unusual intensity of the earthquake, its apparent connection with the great northern boundary-fault of the Highlands, and the possibility of tracing oscillations in successive centres of disturbance along the fault-surface, combined in rendering a detailed investigation desirable. With a few exceptions, the earthquakes originated beneath the district lying between Inverness and the north-eastern end of Loch Ness. The mean direction of the fault, which follows the line of the Great Glen, is N. 35° E. and S. 35° W. and its hade is to the south-east. The isoseismal 8 contains 67 square miles, and its centre is about one-and-a-half miles east-north-east of Dochgarroch and three-quarters of a mile south-east of the fault-line. The correspondence between the position of the great boundary-fault and of the fault inferred from the seismic evidence is so close that there can be little doubt that the earthquake was due to a slip along this fault. The nature of the shock, the sound phenomena, time-relations and after-shocks are described in detail, and some account is added of the earthquakes of 1890 and of sympathetic earthquakes in the valley of the Findhorn. There were two distinct slips in rapid succession, with continuous slight motion between them, the second being greater in amount and extending over an area which probably overlapped, even if it did not entirely include, that within which the first took place. The great slip reached nearly from Loch Ness to Inverness, and was greatest at a point about half-way between. The three chief after-slips resulted in an extension of this area in both directions along the fault-surface, the extension to the north-east being small, while that to the south-west amounted to 6 miles or more. In addition to this migration of the focus, there was also a continuous decrease in the depth of the focus. The earthquakes provide no evidence with regard to the direction of displacement along the boundary-fault. There can be little doubt, however, that Loch Ness is still growing; but it can hardly be determined whether the lake is now contracting in area, or whether it is gradually pushing its way outward to the sea.—The Wood's Point Dyke, Victoria (Australia), by Mr. F. P. Mennell.

Zoological Society, May 6.—Prof. G. B. Howes, F.R.S., vice-president, in the chair.—A note was read by Mr. Roland Trimen, F.R.S., upon a moth of the genus Cossus, which had been reared in the Society's insect-house from a chrysalis sent home from South Africa. The specimen was apparently referable to the common goat-moth of Europe (*Cossus ligniperda*), which had probably been introduced in logs of wood into South Africa.—Mr. Oldfield Thomas, F.R.S., read a paper on the mammals obtained during the Whitaker Expedition to Tripoli. At Mr. J. I. S. Whitaker's expense, Mr. E. Dodson had made a successful collecting expedition into Tripoli, and the specimens of mammals obtained had been presented to the National Museum. Twenty-one species were referred to, and, among others, a hare (*Lepus whitakeri*), allied to *L. aethiopicus*, but of a bright pinkish buffy colour, and a gundi (*Ctenodactylus vali*) like *C. gundi*, but with much larger bullæ, were described as new.—A communication from Mr. G. A. Boulenger, F.R.S., contained lists of four species of fishes, eight species of batrachians and thirty-five species of reptiles, of which specimens had been collected by Mr. J. ffolliott Darling in Mashonaland. Amongst these were described as new two species of fishes (*Labeo darlingi* and *Barbus rhodesianus*), one of batrachians (*Rana darlingi*) and two of reptiles (*Homopus darlingi* and *Ichnotropis longipes*).—A communication was read from Hans Graf von Berlepsch and M. Jean Stolzmann containing a second part of their memoir on the ornithological researches of M. Jean Kalinowski in Central Peru. It gave an account of 188 species and subspecies, of which twelve were described as new.—A paper contributed by Sir Charles Eliot contained notes on the nudibranchs of the eastern and western coasts of Zanzibar. *Zatteria brownii*, *Dunga nodulosa* and *Crosslandia viridis* were described as new genera and species, and remarks were made upon the little-known species *Melibe fimbriata* and *Marrella ferruginosa*.—Prof. G. B. Howes, F.R.S., communicated a paper by Prof. G. Elliot Smith on a case of abnormal dentition in a lemur. The author recorded the occurrence in an individual of *Lemur fulvus* of a fourth lower molar, present on both sides, in its characters a diminutive counterpart of the normal third molar as regards its postero-external cusp. Reverting to the fact that certain fossil lemurs, marsupial-like, possess four molar teeth, and to the presence in Otocyon of four molars, and in the insectivore Centetes of a fourth upper molar, the author asserted a belief in a four-molared ancestry for the Primates.

PARIS.

Academy of Sciences, May 3.—M. Bouquet de la Grye in the chair.—The permanent secretary announced to the Academy the death of M. L. Fuchs, correspondant for the Section of Geometry.—Studies of batteries founded on the use of saline solutions with the reciprocal action of oxidising and reducing liquids, by M. Berthelot.—On the functions of the

sphæridia of the sea-urchin, by M. Yves Delage. Various views have been put forward at different times as to the functions of the sphæridia in sea-urchins. An experimental study has been made with Echinocyamus, and it was found that the sphæridia are not the exclusive organs of the sensation of orientation, since sea-urchins deprived of these organs can turn over as certainly, although less rapidly, than before.—On a class of transformations of Buckland, by M. E. Goursat.—On the deformation of conoids, by M. A. Demoulin.—The problem of surfaces loaded on end. Solution in the case of the cylinder of revolution, by M. Alban Gros.—On the function of self-induction in electric discharges through gases, by M. B. Eginitis.—The action of an intense magnetic field upon the anodic flux, by M. H. Pellat.—The action of self-induction on the spectrum of dissociation of compounds, by M. A. de Gramont. It was found that by altering the self-induction of the spark circuit the spectrum of air could be very easily eliminated without altering that of other bodies. By still further increasing the self-induction of the circuit, the lines due to various metalloids, such as sulphur, selenium, tellurium and phosphorus, could be made to disappear, a result which has obvious applications in the spectroscopic analysis of minerals.—On the law of Maxwell $n^2 = K$ for some compounds containing nitrogen, by M. Edm. van Aubel (see p. 68).—Glucose and the carbonates of cerium. On a new mechanism of oxidation, by M. Andre Job. Cerous carbonate in the presence of air is capable of oxidising arsenites and also glucose. In the latter case the cerous salt behaves like an oxydase.—On the alloys of cadmium with barium and calcium, by M. Henri Gautier.—On an oxycarbide of cerium, by M. Jean Sterba. By the action of carbon upon cerium oxide in the electric furnace, a well-defined crystallised oxycarbide can be obtained of the formula $CeC_2.2CeO_2$. This oxycarbide is relatively stable in water and air, and when decomposed with dilute acids furnishes unsaturated hydrocarbons. No other carbides except this and cerium carbide, CeC_2, can be obtained in the electric furnace.—On arsenic anhydride and its hydrates, by M. V. Auger. The only hydrates which could be obtained were $(H_3AsO_4)_2$, H_2O and $H_6As_4O_{13}$. The three hydrates $HAsO_3$, $H_4As_2O_7$ and H_3AsO_4 described by Kopp could not be prepared.—The preparation and properties of the chloro-, bromo- and iodo-sulphobismuthites of lead, by M. Fernand Ducatte.—On some derivatives of pyruvylpyruvic ester, by M. L. J. Simon. An unsuccessful attempt was made to prepare this ester, $CH_3—CO—CO—CH_2—CO—CO_2C_2H_5$. The product of the action of aniline upon ethyl pyruvate appears to be this triketone condensed with two molecules of aniline. Only one of the aniline groups could be split off by hydrolysis with sulphuric acid.—On the mutual action of acid chlorides and methanal, by M. Marcel Descudé.—On the combinations of sodium tetrazoditolylsulphite with aromatic amines and phenols, and their transformation into azo colouring matters, by MM. A. Seyewetz and Biot.—On the addition of hypochlorous acid to propylene, by M. Louis Henry. A reply to a note of M. Tiffenau on the constitution of the chlorhydrins. The constitution of the addition product of hypochlorous acid to propylene has usually been determined by oxidation. The author points out that the apparently contradictory results obtained are due to the fact that the same compound gives different oxidation products according to the oxidising agent used. It is possible that two addition products are simultaneously formed, but the principal one is undoubtedly that in which the -OH group attaches itself to the group $=CH_2$.—The development of black rot, by M. A. Prunet.—The Carboniferous eruptive rocks of Creuse, by M. L. de Launay. The results of this investigation are in accord with the theory of M. Michel Lévy on the differentiation of magmas.—Study of specimens of water and sea floor from the North Atlantic, by M. J. Thoulet.

DIARY OF SOCIETIES.

THURSDAY, MAY 15.

ROYAL SOCIETY, at 4.30.—On some Phenomena affecting the Transmission of Electric Waves over the Surface of the Sea and Earth: Capt. H. B. Jackson, R.N., F.R.S.—Microscopic Effects of Stress on Platinum: T. Andrews, F.R.S., and C. R. Andrews.—A Note on the Recrystallisation of Platinum: W. Rosenhain.—Cyanogenesis in Plants. Part II. SPACE PERCEPTION.

Studies in Auditory and Visual Space Perception. By Arthur Henry Pierce, Ph.D. Pp. vi + 361. (New York, London and Bombay: Longmans, Green and Co., 1901.) Price 6*s.* 6*d.* net.

THE larger and more interesting part of this book deals with the problem of the localisation of sound. We all know that we, in common with other animals having the sense of hearing, can, with considerable accuracy, determine the direction from which a sound comes to us. We hear a lark, and after a little feeling about, if we may use such an expression, we are certain that the bird is not far from a place in the sky to which we can confidently point, and examining with our eyes the region near that point we soon see the lark.

In all ordinary efforts to find out where the source of sound is, we move our head, either alone or with our body. If the necessary movement is angularly small, we may move the head without moving the body, if it is large we must move the body; so far as the result is concerned it is indifferent how the head is moved, with or without the movement of the body.

What we do is to turn to the side from which the sound comes and continue this movement until the median plane of the head is in such a position that the slightest movement of the median plane will put the source of sound into the right or left hemisphere; we then know that the source of sound is in the median plane and in front. Having thus found a vertical plane containing the source of sound, we have next (and experience seems to show that this is really the order followed) to determine the place of the source of sound in the semicircle in front from zenith to nadir. This *could* be done in a precisely similar way. We might turn our head so that its vertical axis became horizontal and our median plane coincided with the horizontal plane, and now rotating the head about its vertical axis (now horizontal) we could get the source of sound into the median plane of the head. The intersection of the two planes each of which contains the source of sound would, of course, be the line passing through the head and the source of sound. Put more generally, by inclining the head we could find two positions of the median plane of the head each containing the source of sound, and the intersection of these planes is the direction sought. Birds seem to use this method, and it is worthy of note that birds have no concha, but human beings find what may be called the altitude of the source of sound in another way.

If we look at a source of sound, such as a splashing fall of water or a fizzing steam-pipe, the more complex the sound the better, and rotate the head about its right and left axis, so as to look now up, now down, now forward, we find that a very notable change of sound takes place just at the position of the head when we are looking straight at the source of sound. This rather abrupt change of quality of the sound seems to be caused by the acoustic shadow of the tragus. This shadow is, of course, not analogous to the black shadow to which we are accustomed when comparatively large bodies intercept a beam of light, but rather to the coloured shadow due to diffraction, and therefore does not diminish the intensity of the sound, but changes its quality. It may be noted that the tip of the tragus is almost exactly in front of the external meatus. Whether this explanation of the mechanism is correct or not, it seems certain that in locating sounds we do really turn the head (with or without the body) about a vertical axis until we find the source of sound in front, and then look up and down until we are looking at the source.

Now what has just been described is not at all what Prof. Pierce, and most of the authors whose experiments and speculations he discusses, mean by the localisation of sound. What they investigate is the question how far we can, *without moving the head*, determine the position of the source of a sound. All are agreed that we can tell with certainty whether the sound comes from the right or from the left or is in the median plane, but some think this is all, while some, including Prof. Pierce, think a good deal more than this can be made out without moving the head.

One defect in the account of many of these experiments is that no indication is given of how errors arising from involuntary and unconscious movements of the head are guarded against. In the experiments described it is found that the accuracy of localisation is greatest when the source of sound is nearly in front or nearly behind the observer. But these are exactly the positions in which a slight movement of the head gives the greatest help, so that unless care is taken to avoid any, however slight, movement of the head, we can gather little from the experiments as to the accuracy of localisation with the head fixed. There are three ways in which this source of error can be eliminated. First, by making the sound of such short duration that there is no time to turn the head during its continuance. This was the plan adopted by the present writer when he in 1874, at the meeting of the British Association in Belfast, recommended the snapping of two coins as the source of sound, and he is pleased to learn from Prof. Pierce that this form of the experiment is still used as a parlour amusement in America. Second, by mechanically fixing the head. It is difficult, though not impossible, to accomplish this without the introduction of apparatus which will interfere with the uninterrupted access of sound to the ears. Third, by recording any movement of the head which may take place by means of tapes placed round the head, the ends of the tapes being connected with a recording apparatus, so that the movement of the head may be noted. Experiments in which such movement occurred might then be excluded. It is well known that such involuntary and unconscious movements do occur. Most of us have heard of the device by means of which a famous French army surgeon used to detect feigned deafness in unwilling conscripts. He led the supposed deaf man along a stone-paved passage and secretly dropped a coin. The conscript jerked his head a little, on which the surgeon said, "My friend, you are not very deaf, you heard that franc fall." So unless we have some means of ensuring fixity of the head we cannot be certain that the greater accuracy of localisation in some positions is not, partly at least, due to involuntary and unconscious movement of the head.

The experiments on the spatial perception of two simultaneous sounds of similar quality are of special interest. Such sounds coalesce and give rise to a resultant or, as Prof. Pierce aptly calls it, phantom sound. As a rule this phantom sound is located at a position intermediate between those to which the observer would refer the two real components. These experiments with two coalescing sounds, not being liable to the same extent as those with one sound to the error introduced by unconscious movements of the head, may be of use to check such errors and to show that they exist. A very curious case, or set of cases, is examined by Prof. Pierce, who gives very fully the results of his own experiments and of those of other investigators. When the two component sounds, one on each side, are produced near the ears (4 cm. or less from each ear), the phantom is heard *within the cranium* and can be made to move inside the head towards the one or the other ear by varying the relative loudness of the components. When the distance of the two sounds from each of the ears is 8 cm. or more, the phantom is extra-cranial.

What seemed the most interesting points discussed in this essay have been noted; but the whole of it is interesting, and physicists and physiologists will find it well worth careful reading. The fairly complete bibliography annexed to it greatly adds to its value.

The second part of the book deals with some optical illusions, which are discussed with great critical acumen.

ALEX. CRUM BROWN.

THE MORPHOLOGICAL VALUE OF THE CENTROSOME.

Das Problem der Befruchtung. Von Dr. Th. Boveri. Pp. 48. (Jena: Gustav Fischer, 1902.) Price Mk. 1·80.

PROF. BOVERI is so well known as a cytologist that anything from his pen will be read with interest. He is concerned in the little work before us in presenting in a non-technical fashion the main morphological peculiarities connected with fertilisation, and he also discusses the meaning of the processes involved. The appendix will probably be regarded by many as the most interesting part of the whole, as he there critically examines the results which have been obtained by Loeb on artificial parthenogenesis, and which have been confirmed and further investigated by Wilson. It will be within the recollection of some people that Loeb discovered the important fact that it is possible to induce normal development in *unfertilised* eggs of certain marine animals by treating them for some time with a 12 per cent. solution of magnesium chloride in seawater, and then retransferring the eggs to normal seawater. Morgan and others had previously found that the addition of salts of various kinds to the water sufficed to produce bodies remarkably like centrospheres, but it was not until Wilson showed this also to occur in Loeb's experiments, and that they almost certainly initiate the process of segmentation, that the significance of the earlier results became apparent.

Now the egg is normally destitute of any centrosome, and it has been thought on many grounds that one of the chief uses of the sperm was to import this body into the protoplasm of the inert ovum. Boveri himself first put forward this view, and he now seems inclined to admit that it may demand some degree of modification. His original conception of the sperm as starting the cytoplasmic activities remains untouched, but obviously the nature of the mechanism involved is, as he says, open to a different interpretation from that originally assigned to it by himself. For it may now be fairly argued that it is not a centrosome as an *organised structure* which is introduced into the egg, and which there starts the segmentation processes, but rather a chemical substance which, in combination with the ovian cytoplasm, produces the body in question. Such a view would reconcile much that has hitherto been difficult of explanation in connection with the diverse behaviour of centrosomes in different organisms, and even in different cells and tissues of the same individual.

In cycads, for example, centrosome-like structures (blepharoplasts) are associated with the karyokinesis of the generative cell of the pollen tube, but they are absent from the rest of the antecedent cell-generations. Hence their morphological permanence can hardly be seriously maintained in such a case as this. Again, in many of the higher plants the spindle fibres which appear in the early prophases of karyokinesis (*e.g.* in pollen-mother cells of the lily) originate at many different spots in the cell, and this may probably be correlated with the extrusion of nucleolar substance which was described in this instance as long ago as 1893. Furthermore, such a conception of the possible nature of centrosomes enables one to harmonise the peculiar quadripolar spindles so characteristic of the lobed spore-mother cells of many liverworts.

It is clear, of course, that the acceptance of such a possible origin of centrosomes does not necessarily involve a denial of their possible permanence in other cases. But it does add another striking example to those cases in which a morphological character may be traced to physiological causes, the character itself only persisting for so long as the physiological stimulus continues to operate.

J. B. F.

ROSE CULTURE.

The Book of the Rose. By the Rev. A. Foster-Melliar. Second edition, with 33 illustrations. Pp. xiv + 352. (London: Macmillan and Co., Ltd., 1902.) Price 6*s*.

THE design of the author is "to show how roses may be grown in the best possible manner so as to produce the finest blooms"; and from his enthusiastic love and his long, successful culture of the flower, he has written such an exhaustive treatise that the reader who has the ambition, the energy and the means to follow his instructions cannot fail to achieve success. He gives clear and comprehensive details as to soil, situation, selection and treatment, where to erect a throne for the queen of flowers, and the homage which must be paid by those devoted subjects who would win her most gracious smiles. With a loyal service, which is never disheartened, the knight of the rose must be eager to maintain her supremacy against all comers. Without metaphor, he who would grow roses in their perfect beauty, and, like the author of this book, would be rewarded with medals and trophies, must obey the immutable law, must work for his wage, must train for the race if he would so run that he

mây obtain the prize ; he must dig and drain and enrich the soil, must plant, protect and prune, and, like the husbandman, he must have long patience before the harvest comes. He must be prepared for failures and disappointments, for nipping frosts and scorching suns, hailstones and drenching rains, for blight and mildew, fungus and thrip, for aphis and grubs, spiders and beetles, suckers and weeds. The obstacles are many, and the enemies are fierce, as ever to those who would attain excellence.

But perseverance will prevail, and he who has an expert for his guide will reach the summit, however steep may be the mountain. He who has a productive soil, a situation sheltered but not overshadowed, an atmosphere not polluted by smoke or smut, who adds to these inseparable adjuncts of success a determination to succeed, and then follows, in strict obedience, the teaching of Mr. Foster-Melliar, will repeat his achievements ; the pupil will become a professor, and the entered apprentice will be a master-mason.

On the subject of "garden roses," roses which have not the perfect symmetry and fulness required for exhibition at our shows, the author declares that he is no authority, and he tells us little or nothing of their infinite variety and beauty in beds, borders and shrubberies, on pillars, pergolas and walls ; but as a manual for the production of those roses, which have been most admired by rosarians, in their loveliest form, his admirable essay is complete.

OUR BOOK SHELF.

The Birds of North and Middle America. Part i. "The Fringillidæ." By R. Ridgway. *Bulletin* U.S. Museum, No. 50. Pp. 715 ; 20 plates. (Washington, 1901.)

MR. RIDGWAY is such a well-known authority on the birds of North America that anything coming from his pen is sure to obtain a welcome at the hands of his brother ornithologists. The size of the present volume, which, as stated in its title, deals only with a single family, affords an index of the bulk and extent of the work of which it forms the commencement. The amount of labour involved in such a task is enormous and can only be properly appreciated by working naturalists. Preparations for the work, the author tells us, have been in more or less active progress for the last twenty years, and so long ago as the autumn of 1894 the task of putting together in proper form for press the vast accumulation of material was taken in hand. The labour of measuring specimens of more than 3000 forms of birds and making the necessary references to previous descriptions was, however, so vast that it has only been possible to issue the first part after this long lapse of time. It is hoped, now that much of the drudgery is accomplished, future progress may be more rapid.

The object of the work is to describe in detail every definable form of bird—whether species or subspecies—met with on the American continent, from the Arctic districts to the eastern end of the Isthmus of Panama, together with the West Indian and Galapagos Islands. Moreover, besides the indigenous denizens of the area, the accidental or casual visitors, as well as artificially introduced species, are included, so that the list is as full and comprehensive as possible. Needless to say, the work is written on modern American lines, so that the number of forms regarded as entitled to distinction is very great ; while the number of genera and subgenera is likewise unusually large. An especial feature of the work is the large number of forms which are relegated to the rank of subspecies.

As regards the description and keys to the different groups and species, the work appears to be admirably written, the number of specimens of which the measurements are given rendering it especially valuable. Perhaps it was somewhat unnecessary to give a general account of birds and their various orders, but this is a fault on the right side, and the work should prove invaluable to all zoologists on both sides of the Atlantic. In replacing the name "Central America" by the unfamiliar "Middle America" the author may be etymologically right, but if this be the reason of the innovation, it is somewhat curious to find such a change advocated by American naturalists, who are notorious for the contempt with which they treat the synthesis and orthography of scientific names. R. L.

The Lens. A Practical Guide to the Choice, Use and Testing of Photographic Objectives. By T. Bolas, F.C.S., F.I.C., and George E. Brown, F.I.C. Pp. vi + 176. (London : Dawbarn and Ward, Ltd., 1902.) Price 2*s.* 6*d.* net.

THIS is a useful book, not only for beginners in the use of the camera, but for many photographic workers who have never studied the optics of lenses. The elementary treatment of lenses is far in advance of that of most professed English text-books of optics, as from the outset it does not make the assumption of an infinite thinness of lenses, but treats them by the method of Gauss by means of principal planes and principal points. Unfortunately, the authors persist in calling the principal points "nodal" points, a confusion of language which will puzzle students if when they come to the eye they discover that the nodal points of that organ are not the same as the principal points. There are good discussions of the subjects of angle of view, inequality of illumination and "depth of focus." We are glad to see that the authors have summoned up courage to omit "indigo" from the tints of the spectrum. It has long been recognised that there is no indigo tint between the blue and the violet. It is a pity that the authors admit the vulgarism in chapter iv. of writing the aperture-ratios $f/24$, $f/16$, &c., as $f24$, $f16$, &c. On p. 49 they give the notation correctly. The lens diagrams would be improved by cross-hatching the sections of the lenses ; it is impossible by looking at the mere outline, for example, of the composite back lens of Fig. 104A, on p. 91, to tell whether it represents three lenses cemented together or two lenses separated by an air-space. The practical hints on focussing, copying and enlarging are excellent ; and we quite concur in the advice on p. 95 to avoid second-hand lenses. Some admirable examples of the performance of lenses are reproduced in half-tone blocks. That of King Henry VII.'s Chapel on p. 171 is really marvellous.

A Text-book of Geology. By Albert Perry Brigham, A.M., F.G.S.A., Professor of Geology in Colgate University. Pp. 477 ; illustrated. (London : Hirschfeld Brothers, Ltd., 1902.)

ALTHOUGH this work bears on its title-page the name of a London publisher, it is evidently prepared with a view to the requirements of teachers and students in the United States. It forms one of the "Twentieth Century Text-books" edited by Dr. A. F. Nightingale, formerly of Chicago. According to its author's preface, this text-book has been especially prepared as an elementary treatise for secondary schools in America, and it seems admirably adapted for this purpose. While modestly disclaiming any great originality in the plan of the work or novelty in the mode of treatment of geological problems, the author may be

congratulated upon having produced a very clear and readable introduction to the study of geology. The illustrations, many of which are new, are especially excellent, some being from original photographs taken by the author during his travels.

It is only fair to add, however, that while the earlier chapters may be read with advantage by all students of the science in every part of the globe, the part of the book which deals with "historical" or stratigraphical geology is quite unsuited for European students. The sequence of formation described is that of the American continent, and the fossils figured are, almost without exception, American forms. This, while fitting the work for students on the other side of the Atlantic, makes the work of little value, so far as its later chapters go, to English readers.

Elementary Plant Physiology. By D. T. Macdougal Ph.D. Pp. xi + 138. (New York and London: Longmans, Green and Co., 1902.) Price 3*s*. net.

WITHIN the pages of his elementary text-book Prof. Macdougal has collected together a very large number of experiments—so large, indeed, that forty-eight laboratory periods do not by any means exhaust the list. A certain number of these would be included in an ordinary anatomical course, *e.g.* the examination of sections of various parts of the plant, of mycorhiza, &c., while others are merely bionomical observations. The inclusion of these, however, is not so much deprecated, but rather the scant treatment which is meted out to some of the more important activities of the plant. Respiration is practically limited to a few experiments with seeds placed in a retort inverted over mercury; such apparatus precludes any but the roughest quantitative measurement. Again, no practical form of potometer is suggested, and absolutely no mention is made of the movement of protoplasm. Apart from the actual study of the movement, the streaming of protoplasm affords a simple indicator when investigating the action of anæsthetics or of neutral or poisonous gases upon the plant. These inhibiting effects are worked in by the author with growth, and this makes the experiments more complicated and less adapted to measurement.

These omissions are the more disappointing because Prof. Macdougal has the happy knack of giving explicit and full directions in a few sentences, and, further, he takes every opportunity of throwing out suggestions which should lead the student to think for himself and thereby obtain a fuller appreciation of the problems with which he is dealing.

Diagramme der electrischen und magnetischen Zustände und Bewegungen. By F. W. Wüllenweber. Pp. 64 + plates. (Leipzig: J. A. Barth, 1901.)

THIS book, consisting of ten plates and sixty diagrams and descriptive text, is put forward by the author as a contribution to the answers to the questions, What is electricity? and What is magnetism? The diagrams consist of figures representing the lines of force due to various distributions of electricity or magnetism; but in no case is there any quantitative representation attempted. All that we are given is a distribution of arrow heads representing the direction of the ether strains on a molecule. The diagrams being purely qualitative, there is really nothing in the book that a student could not put down himself easily, and frequently with greater accuracy than the author. The conception of lines and tubes of force as treated by Maxwell and Thomson can be most useful and instructive, but as they are given in the present book they can only result in confusion. We are afraid the questions What is electricity? and What is magnetism? are no more nearly answered after the appearance of this book than before.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Remarkable Solar Halo.

ON Sunday, August 7, 1898, being in Norway, I was climbing, with a friend, the upper slopes of the Horntind, above Skogstad, in the well-known Valders route between Christiania and Laerdal, lat. 61° 15′ 30″, long. exactly 6° E. We had reached a height of about 4000 feet above sea level when we saw the very remarkable halo of which I send you the photograph of the copy of a very careful drawing, made on the spot. I first caught site of the halo at 11.30 a.m., on lying down for a short rest on a large flat horizontal stone, but I have no reason to doubt that it had been visible for some time before. The early morning had been brilliantly fine, the air still, and the sun very hot; about 10.30 a.m. a very light breeze from almost due south began to blow, with intervals of dead calm. When the halo was seen, the sky was completely covered with a thin white haze. There was, however, no rain that day, though the weather on the next and succeeding days was not good. The sky outside the circles seemed everywhere brighter than inside them; the sun shone through the haze scarcely brightly enough to throw a distinct shadow, and his rays aroused no sensation of warmth. The inner edge of all the rings was fairly sharp, and of an orange-red colour, brightening into yellow, which

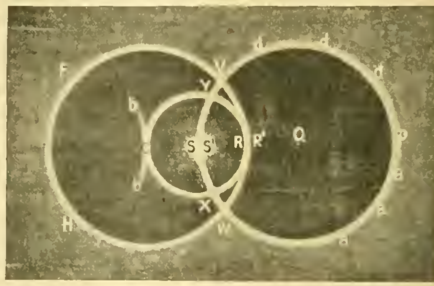

FIG. 1.

grew paler towards the outer rim, where it faded into a bluish-white radiance, which in turn became imperceptibly blended with the white misty sky. The width of the rings was from one-and-a-half to two degrees.

I watched the halo until it had completely faded. First the ring SVPW faded, the other two complete circles remaining visible after it had completely disappeared. Next the ring FHWV slowly vanished, leaving the small ring CYRX quite perfect and bright, and also the luminosity at *bb*. This last looked like a small part of a fourth circle; certainly it was curved and convex towards the sun, but of what radius this small arc was I am uncertain, but suspect that it was either the same, or greater than, the radius of the two big circles. I had no accurate instrument with me at the time for measuring angles, but the disc of the sun was distinctly visible through my neutral-tinted snow glasses, and in estimating the distance S′R as subtending at the eye an angle of 19° I do not think there is an error of more than a few minutes of angle. The radius of each of the big circles must have been, therefore, nearly 44°, and that of the small circle about 22°.

In the illustration, the width of the rings is somewhat exaggerated. But by far the most remarkable thing about this halo is the asymmetric position of the sun with respect to the rings. With respect to the two large circles this is obvious, for the sun appeared to lie on the circumference of one of them, and at a point half way (subject to what is said below) between the centre and the circumference of the other; but, besides this, I could not persuade myself, though I exerted all my powers of

imagination to do so, that the sun was *exactly* in the middle of the *small* circle, and was forced, after repeated observations, to conclude that the sun's centre appeared to be about the ninth part of the distance SR to the west of the true centre S. I can only offer in explanation of this that it was due to some curious, perhaps subjective, effect caused by the part of the arc VYSXW, which was very bright, for *after this ring had vanished* the sun certainly appeared at S, without any alteration that I could see in the position of the two circles left.

There was no trace of any luminosity other than that of the sky at Q. The brightest part of the whole halo, apart from the sun itself and the part of the arc YSX near to the sun, was the arc VRW; but at C, V, Y, X and W, and especially at X and W, the light seemed decidedly brighter than in the other parts of the rings, though there were no proper "mock suns." Since the time when I saw this weird and magnificent display, I have often tried to deduce the observed curves from the known hexagonal forms of ice crystals, and even to produce them empirically by reflecting and refracting light from glass models, but so far without any success. It will be readily seen that the halo bears a certain resemblance to the lunar halo which was the subject of a letter to NATURE of May 1 by Prof. Barnard, but the two are in reality widely different. Probably the form I have just described is of *exceedingly* rare occurrence, for it presents far too grand and curious a spectacle to be visible without exciting attention, and I have never come across any mention or diagram of a halo like it. T. C. PORTER.

Eton, May 8.

Sun-pillar (?)

MISS HERSCHEL (a careful observer) has just called me out to see one. At 7.10 p.m. she saw the sun above a bank of clouds, in a somewhat hazy sky, but no clouds above it for a space of some 5 degrees. Above that was a light-fringed belt of clouds of great depth. From the sun a parallel-sided pillar of light, just like the reflection of the sun in a slightly rippled sea, stood upright into, and stopped at, the light-fringe; it was not so bright as the reflection spoken of would be, but markedly brighter than the background sky; colour yellow. Miss Herschel had to bicycle home three-quarters of a mile uphill to call me, and it was fading before she reached home.

I was prompt, but too late (7.25) to get a good view. The possibility of Martinique dust induces me to send you this. Sunset moderately red; temperature here 42°; air calm all day; with dark sky and damp mistiness. W. J. HERSCHEL.

Littlemore, May 13.

Palæolithic Implements in Ipswich.

ALTHOUGH in isolated cases implements of Palæolithic workmanship have occasionally been found in Ipswich, it is only during the last few weeks that a deposit containing abundant Palæolithic remains has been discovered.

On March 21 last, after long searching, I was fortunate enough to hit upon this interesting site, and the result has been a harvest of implements of very varied types. Mr. Clement Reid, whom I acquainted with the discovery, at once came down to examine the spot, and under his guidance it will be carefully studied.

The relations of the deposits remain to be worked out, but so far show some resemblance to those found at Hoxne and Hitchin.

Among the implements found, some have a thick, ochreous patina, while others are almost devoid of it. Most are very slightly rolled, but some are still sharp.

Pointed implements roughly worked at the butt predominate, but in one case the butt-end has been carefully sharpened.

A fine oval implement shows signs of having been worked for hafting, as also does a smaller chisel-like form. Implements corresponding to those described by Sir John Evans as "crescent like," a boring implement, a possible sling-stone, several ovoid forms flat on one side and raised on the other, triangular forms, some thick and heavy, one flat, and a delicate leaf-shaped implement, show the variety of purposes which these flints were made to serve.

The position occupied by the Palæolithic remains appears to be that of a silted-up channel cut through Glacial deposits. Some of the implements were found at a depth of 12½ feet, others considerably higher, which may account for the difference in their condition. NINA FRANCES LAYARD.

Brückner's Cycle and the Variation of Temperature in Europe.

WE now possess excellent long series of weather-observations for many places. It occurred to me lately to apply to several of the annual temperature series in Europe an averaging process which would tend to bring out the larger waves of variation, or at least to show how year-groups of a given magnitude compare with one another. I have accordingly considered in groups of ten years (1 to 10, 2 to 11, 3 to 12, and so on) the following (see diagram):—A. Annual mean temperature of Greenwich (from 1841). B. That of Geneva (from 1826). C. That of Bremen (from 1829). D. That of Vienna (from 1826).

[The Greenwich curve is drawn on a larger scale than the others. The degrees are Fahr., those of the others Cent. The position of the curves is simply contrived so that they should not cross one another. In the case of Vienna, the continuous curve from 1855 is for the Hohe Warte near Vienna; the previous dotted curve is *approximate* for the same place, deduced from data of the University Observatory in Vienna. The Bremen figures used extend only to 1895, the other series to 1900.]

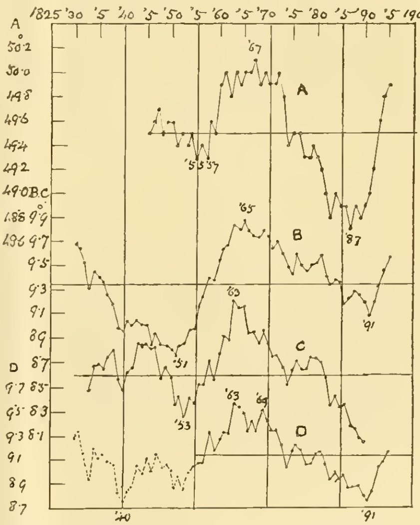

FIG. 1.—A, Greenwich; B, Geneva; C, Bremen; D, Vienna.

Taking the case of Greenwich, it will be understood that the first point, for 1845, indicates the average mean temperature of the ten years 1841 to 1850, the second that of 1842 to 1851, and so on.

The curves, it will be seen, all agree in showing a long wave with crest in the sixties, and extending from a minimum in the fifties (Vienna a little earlier) to another about the end of the eighties (or beginning of nineties).

The Greenwich maximum is reached in 1867, and minima are found at, say, 1855 and 1887. The temperatures prior to 1841 are in some uncertainty; but we should probably be safe in saying that an earlier minimum, of magnitude corresponding rather to the last, occurred about 1816. Thus we have 1816–55 = 39 years; 1855–87 = 32 years; which agrees very fairly with Brückner's cycle of about 35 years. As to previous maxima, we may probably reckon one in the later twenties. The curve (with final point in 1895) would appear to be now near a second maximum from that date (? 1902); and we might with some reason, perhaps, look for another minimum, or conspicuously cold group, in the early twenties of this century.

The minimum of 1855 for Greenwich is considerably less pronounced than that of 1887, and in Bremen, too, the earlier

minimum seems to have been less than the later; while in Geneva the earlier minimum is the deeper.

The facts above given may be usefully compared with Dr. Lockyer's recent important researches, pointing to a cycle of about thirty-five years in the sun-spot variations. It may be doubted if the annual mean temperature of these European stations shows any good evidence of being ruled by the eleven-year cycle of sun-spots; and if it did, the method of smoothing here adopted might even obscure such an effect somewhat. This, however, does not seem to affect the validity of evidence from other orders of data. ALEX. B. MACDOWALL.

Resultant Tones and the Harmonic Series.

IN reply to Prof. Thompson's criticism of the plan of recovering differential resultant tones by means of the harmonic series, may I say that my position is that of a road-maker, not a discoverer—a Macadam rather than a Columbus.

So long as authorities teach that resultant tones have a vibration frequency which is equal to the difference between the vibration frequencies of their generators, so long will the harmonic series afford an easier means to the same end.

This applies also, of course, to summational tones.

The question whether these latter are only "one of the myths of science" or not I leave to abler heads than mine to decide.

Meanwhile, the fact that the perfect fourth, the minor third and the minor sixth give, as the sum of their vibration frequencies, a vibration frequency which is intermediate between two notes, thus exactly agreeing with the harmonic series, $3 + 4 = 7$, $5 + 6 = 11$ and $5 + 8 = 13$, is at least interesting.

MARGARET DICKINS.

Tardebigge Vicarage, Bromsgrove, May 9.

Magic Squares.

HAVING attempted some years ago to determine the number of magic squares of five having a nucleus forming a magic square of three, I was interested to find that further progress towards a solution of the problem has been made by your correspondent Mr. C. Planck, who seems to have found fifty-one solutions more than I from the same twenty-six nuclei, whereas I have only in one case, namely for the nucleus R (5, 7), found one more solution than he. The twenty-one solutions for this nucleus are appended in the following table, from which both the equations and the numbers forming the first row and the first column of the border may be read off without difficulty, if the first dotted number be put at the head of the column, and at the foot of the same the complement of the second. Thus, from the first row of the table,

$$1 . \dot{2} . \dot{4} . 6 . \overline{12} \mid \bar{3} . 8 . 10$$

we gather that the first row of five minors (numbers less than 13) may be converted into a normal row with sum 5×13 by replacing the three barred numbers by their complements, since $2 + 4 + 13 = 1 + 6 + 12$, whilst the remaining three minors, together with the dotted pair, furnish a normal column when 4 and 3 are replaced by their complements, since here again $4 + 3 + 13 = 2 + 8 + 10$. The border with nucleus, accordingly, when completed, is

	a	b		b'	a'
a	2	25	20	14	4
b	8	11	21	7	18
	10	9	13	17	16
b'	23	19	5	15	3
a'	22	1	6	12	24

1	$\bar{1}$	$\dot{2}$	$\dot{4}$	$\bar{6}$	$\overline{12}$	$\bar{3}$	8	10
2	$\bar{1}$	$\dot{2}$	$\dot{4}$	$\bar{8}$	$\overline{10}$	3	6	12
3	1	$\dot{2}$	$\bar{4}$	$\dot{6}$	10	3	8	12
4	$\dot{2}$	3	$\bar{4}$	$\dot{6}$	12	$\bar{1}$	8	10
5	$\bar{1}$	$\dot{2}$	$\dot{6}$	8	$\overline{12}$	$\bar{3}$	4	$\overline{10}$
6	$\dot{2}$	$\bar{3}$	$\dot{6}$	$\bar{8}$	$\overline{10}$	$\bar{1}$	4	$\overline{12}$
7	$\dot{2}$	$\bar{3}$	$\bar{4}$	$\dot{8}$	10	$\bar{1}$	6	$\overline{12}$
8	$\dot{2}$	3	$\bar{6}$	$\dot{8}$	12	$\bar{1}$	4	$\overline{10}$
9	$\bar{1}$	2	8	$\overline{10}$	12	3	$\bar{4}$	$\bar{6}$
10	$\dot{2}$	$\bar{3}$	$\bar{4}$	6	$\dot{12}$	1	8	$\overline{10}$
11	$\dot{2}$	3	$\bar{8}$	10	$\dot{12}$	$\bar{1}$	4	$\bar{6}$
12	1	$\dot{4}$	$\dot{6}$	8	12	2	3	10
13	3	$\dot{4}$	$\dot{6}$	$\bar{8}$	$\overline{12}$	1	$\bar{2}$	$\overline{10}$
14	$\bar{1}$	$\dot{4}$	8	$\overline{10}$	$\dot{12}$	2	3	$\dot{6}$
15	$\bar{1}$	2	$\bar{4}$	$\dot{6}$	$\dot{10}$	$\bar{3}$	8	12
16	1	$\bar{2}$	4	$\dot{8}$	$\dot{10}$	$\bar{3}$	6	12
17	1	2	$\bar{6}$	$\dot{8}$	$\dot{10}$	$\bar{3}$	4	$\overline{12}$
18	2	3	$\bar{6}$	$\dot{8}$	$\dot{10}$	$\bar{1}$	4	12
19	$\bar{3}$	4	$\bar{6}$	$\dot{8}$	$\dot{10}$	$\bar{1}$	2	12
20	1	2	6	$\dot{8}$	$\dot{12}$	$\bar{3}$	4	$\overline{10}$
21	3	$\bar{4}$	6	$\dot{8}$	$\dot{12}$	1	2	10

When the number 603 is multiplied by 288 we get 173,664 for the number of such nuclear squares. When we proceed to inquire as to the number of all types of magic squares of five, we must begin by doubling the above number, since every magic square with odd root may be varied by permuting the rows above the mid-row, together with the rows below the same, and at the same time the columns on either side of the mid-column, so that the above square may be transformed by reversing the order of the marginal letters a, b and a', b', as follows:—

	b	a		a'	b'
b	11	8	21	18	7
a	25	2	20	4	14
	9	10	13	16	17
a'	1	22	6	24	12
b'	19	23	5	3	15

If now we add to the number 347,328 thus obtained the squares in which each row and each column contains all the units 1 . 2 . . 5 increased by the four increments 5 . 10 . 15 . 20 without repetitions of either, of which there are at least 21,376, we get 368,704 without considering other types, probably some hundreds of thousands in number, which would certainly bring the minimum to more than half a million.

Shipley, Yorks. J. WILLIS.

Mont Pelée and After-Glow.

MAY I point out that the after-glow following the eruption of Krakatoa was—as I wrote at the time—remarkably emphasised on the west coast of British India.

Following the letter of Dr. W. J. S. Lockyer in NATURE of May 15, the after-glow, now, after the eruption of Mont Pelée (and Soufrière ?) should be as remarkably emphasised in central and perhaps the southern part of North America.

In Europe this eruption will not (?) cause the same effect as to after-glow as the former. F. C. CONSTABLE.

Wick Court, near Bristol, May 18.

THE VOLCANIC ERUPTIONS IN THE WEST INDIES.

SINCE we went to press last week further details have become available as to the volcanic disaster in the West Indies. We give a summary of the reports which have been published in the *Times* during the past week upon the sequence and character of the eruptions from the commencement of the disturbances, the particulars here given being supplementary to those in our last issue.

April.—In the last days of April smoke was noticed on Mont Pelée and rumbling sounds were heard.

May 3.—Mont Pelée threw out dense masses of steam. Next morning the sky was dark with clouds and ashes. Ashes fell on St. Pierre, which by evening was covered a quarter of an inch thick. The mountain was invisible.

May 4.—A sea-breeze swept the ashy fog from St. Pierre, but at evening dust and scoria fell again.

May 5.—A stream of lava 20 feet high suddenly rushed down the south-western slope of Mont Pelée, and, following the dry bed of the River Blanche, swept away buildings, plantations and people in a tremendous rush to the sea, five miles distant. It was all over in three minutes. The Guérin factory on the beach near the mouth of the river was embedded in lava ; only the chimney could be seen. The sea then receded along the western coast a distance of 100 yards, and returning invaded St. Pierre.

May 5, *St. Vincent.*—The lake in the old crater of the Soufrière became greatly disturbed.

May 6, *St. Vincent.*—At 2 o'clock in the afternoon the Soufrière began a series of volcanic efforts. Severe earthquakes accompanied these. Terrible noises and detonations succeeded quickly, and at 7 p.m. an immense column of steam issued from the crater, continuing until midnight.

May 7, *St. Vincent.*—Terrific explosions occurred, and at 7 a.m. there was another sudden violent escape of steam. This ascended for three hours, when a quantity of material matter was ejected. At noon three craters appeared to open and began to vomit lava. Tremendous detonations followed in quick succession, rapidly merging into a continuous roar. The thundering was heard throughout the Caribbean Sea.

A huge cloud in dark dense columns charged with volcanic matter rose to a height of eight miles from the mountain top, and darkness like midnight descended. The sulphurous air was laden with fine dust, and black rain followed the rain of scoriæ, rocks and stones.

May 8, *Fort de France.*—St. Pierre was within ten minutes annihilated by a terrible volcanic torrent from Mont Pelée and by a combination of suffocating heat, noxious vapours, a shower of burning cinders, and a discharge of burning stones, which reached even to Fort de France.

May 13, *St. Vincent.*—The Soufrière is still in eruption. The reports of the explosions, resembling a terrific cannonade, can be heard at a distance of 100 miles. Following the explosions are columns of steam, which rise miles in height, and immense luminous bombs also issue from the crater. Lightning is playing fiercely in the upper sky.

May 15, *Fort de France.*—Mont Pelée continues in a state of eruption, but the wind is now carrying the smoke and the greater part of the matter thrown out to the north, thus relieving the parties of workers at St. Pierre.

May 15, *Kingston, Jamaica.*—For some days past the atmosphere here has been peculiarly hazy and sombre and the temperature very high, which was thought to be due to dust brought by winds from the volcanoes. This is now proved to be the case, dust being detected falling on the hills, which on microscopic examination is shown to be volcanic ash.

May 15, *St. Vincent.*—The entire northern part of the island is covered with ashes averaging 18 inches in depth, and varying from a thin layer at Kingstown to 24 inches or more at Georgetown. The streets of Georgetown are encumbered with heaps of ashes like snow-drifts, and several roofs have fallen in from the weight of the deposits upon them.

May 15, *Fort de France.*—At intervals Mont Pelée and Lacroix, 1350 metres high, are visible. Now that all the points of eruption can be discerned, seven craters can be seen which seem still active. Yesterday a flow of lava 400 metres wide descended as far as White River, its foaming sound being audible to a great distance. A new crater is perceptible near the shore, pouring out blinding steam. The sea, affected by the disturbances of all the streams, seems itself troubled, invades Prêcheur, and, undermining several houses, adds the ravages of inundation to those of fire. On the other hand, the flow of lava drives back the bay 20 metres and increases the area of devastation.

May 17, *St. Vincent.*—The bed of the lava in the windward district is still hot. An abyss 500 feet deep by 200 feet wide, which existed between Langly Park and Rabacci, is filled with lava, and the physical features of the mountain side are apparently more beautiful than before the eruption. A curious feature is that the earthquakes were not general. While at Château Belair there were, before the eruption, continuous convulsions every few hours, in Kingstown and Georgetown there were only sixty shocks in four hours.

Although it resulted in fewer fatalities, the eruption of the Soufrière was no less violent than that of Mont Pelée. Sixteen square miles are covered with lava.

May 19, *St. Thomas.*—A further serious eruption of Mont Pelée occurred. The search parties at St. Pierre were compelled to leave at once.

May 20, *St. Thomas.*—Very loud detonations were heard in Dominica, Guadeloupe, Antigua and St. Kitts, and faintly in St. Thomas. At St. Thomas the sounds heard were louder than those of May 7.

There is great reason to hope that a small scientific party from England will be promptly despatched to investigate the terrible volcanic outbursts in the West Indies. The idea was mooted in conversation in the ante-room of the Royal Society at last week's meeting, and Dr. Tempest Anderson, who probably has examined and photographed volcanic phenomena in more regions than any other Englishman, at once expressed his readiness to undertake the journey. Strong hope is entertained that leave of absence may be granted to Dr. Flett, petrologist to the Geological Survey, to join in the investigation, the expenses of which might be defrayed, notwithstanding some technical difficulties, from the Government Grant. It is to be hoped these may be overcome, because no time should be lost, and the party should start by the next boat on May 28. They will naturally go first to St. Vincent and endeavour to obtain trustworthy accounts of the eruption of the Soufrière, to ascertain the changes which have been made in the physical geography of the district, and to collect specimens of the materials ejected, as far as possible in chronological order. But we may hope that they will not restrict themselves to the British Island. The eruption at Mont Pelée in Martinique has been, not only more destructive to life, but also, according to what has been published, more abnormal in its phenomena. So contradictory are the reports that it is at present almost impossible to say what really has happened, beyond the one melancholy fact that a paroxysm in an eruption of unusual violence has caused unwonted devastation and fearful loss of life. By examination on the spot, by conference with other scientific investigators, who may already have reached the island from America or France, rumours may be sifted and evidence obtained from examination of the materials beneath which St. Pierre has been buried. A good collection of them, and other ejectamenta of the volcano, will be of great value. A comparison of those from the two islands may throw light on some interesting

and important questions. The fact that the eruptions have been almost simultaneous suggests that the orifices are situated on the same fissure, but it is, of course, possible that they may indicate a zone rather than a line of weakness in the earth's crust, and so may not have tapped precisely the same source of supply. Again, both eruptions have been preceded by a long pause, during which a column of heated material may have been kept standing for several years in the "neck" of the volcanoes. If so that would be very favourable to magmatic differentiation, and this might be revealed on chemical and microscopic examination of the materials discharged during the successive stages of the eruptions. Dr. Tempest Anderson's wide experience as a traveller, especially in volcanic districts, with his skill as a photographer, and Dr. Flett's intimate knowledge of all sides of petrology, will ensure, by their working in combination, that nothing will be missed, and important accessions be made to our knowledge of vulcanology. The shortness of the time before starting is the main difficulty, but as the enterprise is said to be favourably regarded by the Colonial Office and the officers of the Royal Society, and is heartily backed by several London geologists, technical difficulties should not prove insuperable.

There are various signs that the eruptions in the West Indies are connected with the occurrence of other terrestrial and cosmic phenomena. A report in the *Daily Mail* states that the mineral spring waters at Teplitz, Bohemia, turned brown suddenly last week. A similar phenomenon was observed before the great earthquake at Lisbon in 1755, and a repetition of the disaster is feared.

Telegraphic communication between Karachi and the rest of India has been interrupted for four days by the occurrence of the most severe and destructive storm ever known in Sind. Upwards of 40 miles of the Sind Railway have been washed away, bridges and embankments have disappeared, and the telegraph line for 50 miles either completely vanished or hopelessly dismantled

There has been a great storm in the United States. A telegram from Goliad, Texas, states that on May 18, at 3.45 p.m., a tornado, preceded by heavy hail, swept over the town and caused great destruction. The storm lasted only five minutes. It came from the south-east without warning, and travelled as far as Kentucky, traversing four States.

Also from the United States news has been received of a great mining disaster. On May 19, at 7.30 a.m., the Fraterville and Thistle coal mines at Coalcreek, Tennessee, exploded, causing the death of about three hundred men at work in them. Rescue parties have been unable to penetrate far into the mines on account of stifling smoke and gas and extreme heat.

Mr. W. Eddy, of New York, reports that on May 15 a slight earth tremor affected three of his seismographs, the wave coming from the south-east.

All these disturbances are possibly related to a common cause, as suggested by Sir Norman Lockyer in the following letter, which appeared in Monday's *Times* :—

THE WEST INDIAN ERUPTIONS AND SOLAR ENERGY.

Sir,—In 1883, in connection with the eruption of Krakatoa, you were good enough to allow me to appeal through your quickly and widely circulated columns for early information to enable me to test an idea connected with the spread of the glorious sunsets round the world which followed the event.

Because the terrible catastrophes in Martinique and St. Vincent occurred at a well-defined sun-spot *minimum* I was led to inquire whether similar coincidences were to be traced in the past. I did not know then, but I know now, that Wolf, exactly half a century ago, had suggested a connection between solar and seismic activity ; in his time, however, the record of solar changes was short and imperfect.

In my own inquiry I have used our most recently compiled tables, which are now complete for the last seventy years, and I have only considered seismic disturbances within that period. I find it beyond question that the most disastrous volcanic eruptions and earthquakes generally occur, like the rain pulses in India, round the dates of the sun-spot *maximum* and *minimum*. More than this, the 35-year solar period established by Dr. Lockyer, which corresponds approximately with Bruckner's meteorological cycle, can also be obviously traced, so that, indeed, the intensification of the phenomena at the *minimum* of 1867 is now being repeated.

In 1867, Mauna Loa, South America, Formosa, Vesuvius were among the regions involved ; in the West Indies it was the turn of St. Thomas. The many announcements of earthquakes in the present year before the catastrophe of St. Pierre will be in the recollection of everybody.

In the *maximum* in 1871–72, to name only West Indian stations, Martinique first and then St. Vincent followed suit ; in the next *maximum*, in 1883, came Krakatoa.

At Tokio, in a country where the most perfect seismological observatories exist, we find that at times near both sun-spot *maxima* and *minima* the greatest number of disturbances have been recorded.

Very fortunately, the magnificent work of the Indian Meteorological Department enables us to associate the solar changes with pressures in the tropics, and obviously these pressures have to be taken into account and carefully studied.

This, Sir, brings me to the point of this letter, which is, through your kindness, to ask from meteorological observers in the West Indies and the surrounding regions the favour of copies of their barometrical readings, showing the departures from the local means for the two months preceding the eruption at St. Pierre. In this way one or two years may be saved in getting at the facts.

I am, Sir, your obedient servant,

NORMAN LOCKYER.

Solar Physics Observatory, May 17.

MOUNTAIN MASSES AND LATITUDE DETERMINATIONS.[1]

WHEN we take a comprehensive view of the information that has been collected in order to determine the mean figure of the earth, we must acknowledge the important part that has been played by a long succession of Indian geodesists. For practically a century, with greater or less vigour, according to the political conditions prevailing at the time, continuous measurements have been carried on, with the result that we have at least eight meridional and four longitudinal arcs available for the general discussion. The differences of latitude extend from roughly 9° to 20° north, and include the determination of the astronomical latitude of some 150 stations, while the amplitude of the longitudinal arcs embraces nearly 25°, necessitating the investigation of fifty differences of longitude. The vigour displayed is the more curious since it must have been anticipated that the results would be affected with systematic error, as the deflection of the plumb-line would be materially influenced by local circumstances. Not only are the evident masses of the Himalayan range and the Tibetan plateau exercising an effect, which may, perhaps, be allowed for satisfactorily on the assumption of a uniform distribution of density in the strata below the surface, but the presence of the Indian Ocean on two sides of the peninsula, with its varying and uncertain depths, emphasises the difficulties of adjustment and compensation.

Since, however, in order to obtain the full value of the admirable work that has been accomplished in India, it is necessary to eliminate the effect of local attraction, various attempts have been made by different authorities, with, it must be admitted, only partial success. It is a matter of ancient, but of interesting, history to recall the suggestions and the controversy between Archdeacon Pratt and the late Astronomer Royal, the views of neither authority now being acceptable in their entirety, though

[1] "The Attractions of the Himalaya Mountains upon the Plumb-line in India. Considerations of recent Data." By Major S. G. Burrard, Royal Engineers, Superintendent Trigonometrical Surveys. Pp. vii + 115. (Dehra Dun, 1901).

Airy, guided by the insufficiency of the Archdeacon's results to explain the numerical discrepancies, was fully justified in asserting that the magnitudes of attractions computed on the theory of gravitation would be too great. He was less happy in the reason assigned for this conclusion. Airy seems to have considered that the Himalaya Mountains were floating in a sea of dense lava, and that the bases of the mountains displaced a quantity of denser material, much in the same way that an iceberg displaces the water of the ocean on which it floats. The more legitimate explanation seems to be that the elevations are composed largely of an expansion of the matter in the immediately subjacent strata of the earth's crust, the masses above and below being mutually interdependent; where high elevations exist, therefore, the strata below are deficient in density, having parted with some of their contents. At low elevations the density is normal, since there is no appreciable upheaval of matter, while under the sea there is a contraction of matter and consequently an increase of density. These views have generally been supported by the pendulum experiments of Von Sterneck in the neighbourhood of the Alps and the still more recent measurements carried out near Kolberg in connection with the German geodetic operations. The misfortune, however, in all these inquiries is that it is impossible to detect the distance below the surface at which the excess or defect of matter may exist, and, therefore, the intimate connection between the unevenness in the earth's crust and the unequal distribution of subjacent material is not clearly demonstrated.

But in India, the very wealth of observation spread over a district so wide introduces new difficulties and taxes ingenuity to the utmost. The latest authority to struggle with the problem is Major S. G. Burrard, already well known to geodesists for the skill with which he unravelled the perplexities connected with the collimation of the transit instruments used in the longitude inquiries, and later for the very successful determination of the longitude of Madras, in which the circuit errors are reduced to a minimum. One therefore watches his attempt to deal with this old problem with a great deal of interest, and is inclined to treat his deductions with considerable respect.

The particular point at issue may be stated thus: How is the astronomical zenith situated with regard to the geodetic zenith at the principal station for reference of latitude in India? This station is Kalianpur, the astronomical latitude of which, after complete discussion, had been settled at 24° 7′ 11″·10, and from this quantity, by the aid of observed azimuths and the constants of Clarke's spheroid, the geodetic latitudes of all the fundamental stations have been computed. An examination of the results shows that the mean excess of the astronomical over the geodetic values of latitude is −2″·0, or, put in another way, it is shown that of the 148 astronomical latitudes available for geodetic investigation, there are 90 cases of negative excess to 58 of positive. It appeared, therefore, to the late General Walker, and his conclusion has been generally accepted, that the astronomical latitude of Kalianpur was too great by 2″, and that the plumb-line was not deflected to the north, under the influence of the Himalaya Mountains, but was in reality deflected to the south. With the view of settling the question, he recommended that the latitude of a number of subsidiary stations within a moderate distance of the central station should be derived, and the mean latitude be used for the central station, since it might be assumed that such a final result would be more free from the effects of deflection than the latitude of any single point. Such a view regards the deflection as arising from local causes operative over a small area, but Sir David Gill has since pointed out the very obvious objection that if local attraction is persistent in one direction over large continuous areas, group observations such as those recommended would be insufficient to eliminate the effects, and it is not the least important part of Major Burrard's investigation to show that the latent causes of disturbances must be sought over very extended areas.

This work of latitude determination has now been completed under the superintendence of Captain L. Conyngham, and Kalianpur has been surrounded by a chain of stations, of which four are situated at an average distance of nine miles and four at an average distance of thirty-five, and the unexpected result of the discussion is to show that local attraction causes a northerly deflection of the plumb-line to the amount of 0″·60, thus differing by 2″·60 from the value found by General Walker drawn from the whole of the Indian observations. The results in the prime vertical are not less contradictory, and in the following table is exhibited the amount of deflection in the two planes, at each of the group of latitude stations around Kalianpur, situated within the extreme parallels 23° 36′ to 24° 38′:—

	Deflection in the Meridian.		Deflection in the Prime Vertical.	
	The Group System.	Whole of India System.	The Group System.	Whole of India System.
	″	″	″	″
Daiadhari	+1·01 S.	+3·61 S.	+2·13 W.	+5·35 W.
Surantal	+0·82 S.	+3·42 S.	+3·64 W.	+6·86 W.
Sironj	+1·69 S.	+4·29 S.	+2·54 W.	+5·76 W.
Bhaorasa	+1·17 S.	+3·77 S.	+0·22 W.	+3·44 W.
Kalianpur	−0·60 N.	+2·00 S.	−0·22 E.	+3·00 W.
Losalli	−1·02 N.	+1·58 S.	−6·38 E.	−3·16 E.
Tinsia	+0·98 S.	+3·58 S.	—	—
Salot	—	—	−4·49 E.	−1·27 E.
Kamkhera	−2·15 N.	+0·45 S.	+0·04 W.	+3·26 W.
Ahmadpur	−2·49 N.	+0·11 S.	+2·27 W.	+5·49 W.

The stations in this table proceed regularly from the north towards the south, and, confining attention solely to the deflections in the plane of the meridian, it is clear that north of Kalianpur we get a southerly deflection, while on the southern side the plumb-line tends to the north. Clearly, then, the Himalaya chain, which has been so frequently invoked to explain inconvenient discrepancies, will not avail here. And the insufficiency of such a hypothesis is still more clearly shown if the deflections be examined at stations nearer to the mountains. At Dehra Dun, the most northerly, in latitude 30° 19′, the deflection is 38″; in latitude 29° 31′, the deflection is reduced to 7″, and disappears entirely in latitude 27° 51′; while south of Kalianpur we meet with northerly deflections diminishing in amount as Cape Comorin is approached. Major Burrard clearly puts the dilemma thus: "If Himalayan attraction is capable of producing a deflection of 38″ at Dehra Dun, its effects must be felt at Cape Comorin; on the other hand, if Himalayan attraction exercises no effect on plumb-lines south of latitude 29° 31′, it cannot produce a deflection of 38″ at Dehra Dun."

We cannot follow Major Burrard through the various steps by which he seeks to remove the anomalous results, but his method is as exhaustive in theory as it is laborious in practice. He considers the effect of the surrounding ocean on the derived longitudes, and shows that these results stubbornly enforce the necessity of admitting the entire compensation of the ocean. He also asks whether it is possible to introduce any admissible alteration in the dimensions and ellipticity of Clarke's spheroid, and the answer is not less certain. He finds that Clarke's major axis is the most suitable for the Indian longitude arcs, and that, as concerns latitude, while one belt of negative maxima requires an ellipticity greater than 1/289, the large sub-Himalayan deflections demand an ellipticity smaller than 1/311. He therefore concludes that the accepted spheroid is not a source of serious error, and that the Indian observed latitudes favour the Clarke spheroid.

Finally, the author is driven to the conclusion that the undiscovered cause of disturbance is traceable to a great invisible chain of excessive density, traversing India from Balasore, near the mouth of the Hooghly, to Jodhpur in Rajputana, and underlying Mandla and Bhopal, or roughly running parallel with the Himalayan chain. This hypothesis is supported by the observation or detection of the opposite effects on either side of the hidden chain. Between the parallels 24° and 26°, the plumb-lines are deflected southwards, while between the parallels 21° and 18°, the deflections are north and large. This view is further confirmed by the arc of longitude between Amritsur and Mooltan, for the plumb-line at these stations is deflected inwards towards the low-lying alluvium and away from the mountain masses.

The author gives a table in which is shown the amount of deflection due to the Himalayas, to the Tibetan plateau and to the underground chain, and the algebraical sum of these three effects agrees very closely with the observed discrepancies throughout the whole range of latitude, from 30° 19′ in the north to 8° 9′ at the southern end of the arc. It is assumed in this calculation that the northern and southern slopes of the underground chain are inclined at the same angle to the vertical—a somewhat improbable hypothesis, as the author is aware—but it seems not unlikely that further discussion will disclose the contour of this subterranean chain. The particular claim that Major Burrard has on our gratitude is that he sweeps away the accidental and local attractions that have too frequently been put forward to explain isolated discordant instances, and substitutes one general central cause, which can be confirmed or displaced by further investigation.

SCHOOLS AND SCHOLARSHIPS.

THE receipt of a copy of the new issue of "The School Calendar" (London: Whittaker and Co.) suggested the idea that it would be useful and interesting to extract some information from its pages as to the present position of science at the older universities in regard to the awards of scholarships. And it seemed all the better worth while to attempt this because such statistics as have previously come under our notice distinctly suggest that science is now doing a good deal more for the colleges as a whole by helping to maintain their overflowing numbers, than the colleges do for science in distributing their scholarship funds.

Everyone who is interested in this subject knows very well that a generation or so ago the colleges at Oxford and Cambridge did much to promote the teaching of science in schools, and especially in certain schools, by offering science scholarships in numbers that, for the time being, were not only sufficient, but liberal, and that the results of this policy have been beneficial alike to the colleges and to the students of science who were thus attracted to the universities. This action has, in fact, been so successful that at Cambridge the science tripos is, if not the largest, at any rate substantially equal to its older rivals in numbers, and also in the quality of its members, as is shown by the army of able teachers and investigators which the university has produced during the last thirty years or so.

The experiment made in the nineteenth century then has certainly been a considerable success; it has encouraged many able students, stimulated the science work of schools, and extended the field of usefulness of the universities.. But it is a long while since the experiment was begun, and perhaps the time has come to ask whether all is now well; whether the methods of selecting science scholars are satisfactory to the colleges and fair to the candidates, whether the examinations secure a sufficiently good standard in science without tempting the candidates to specialise unduly; whether this work, which was, we believe, initiated by some of the colleges only, is now being helped on by all; and, finally, whether the scholarships offered to those who desire to read in science at the universities are reasonably equal to those offered to students in classics and mathematics.

The little book before us does not afford answers to all these questions, but it contains a great mass of useful information, and within its pages will be found full details concerning the various scholarships that are to be awarded at Oxford and Cambridge during the current year. These, however, we are sorry to add, do not afford very encouraging reading.

Thus we find from the "School Calendar" that at Oxford no less than ten colleges out of twenty offer no scholarships or exhibitions for science at all, and that of the other ten, one important college, which disposes about twenty-eight scholarships and exhibitions, without counting those reserved for students of divinity, only encourages science to the very modest extent of dividing two scholarships between candidates in classics, mathematics, history and science, whilst the remainder are reserved for classics and mathematics. Some of these scholarships, doubtless, are on special foundations, but there are twelve which appear to be under the free control of the college, and all these are allotted to the older branches. At this college about 1700*l.* are to be distributed between classics and mathematics, while classics, mathematics, history and science will have equal chances, may be, in the distribution of 160*l.*

Again, fourteen Oxford colleges offer their scholarships for definite subjects in advance. These offer fifty-nine scholarships or exhibitions valued at 4217*l.* for classics, ten of the total value of 790*l.* for mathematics, eight of the value of 585*l.* for science, and ten of the value of 670*l.* for history. Whilst if we take the grand total for the twenty colleges, and assume that Magdalen, Jesus and Corpus Christi will together devote as many as four scholarships or exhibitions to science, we find that out of one hundred and forty, or more, scholarships, &c., which have a total value above 10,000*l.*, only twelve, having a value of rather less than 850*l.*, are offered for science subjects. These numbers, it should be added, though near to the truth, are only approximations, as in certain cases the number and value of the scholarships offered are subject to modification. The former figure, however, is below and the latter above the actual result of our computation, and the latter would be smaller did we not make the liberal assumption that Magdalen, Jesus and Corpus Christi will give half as many science scholarships as all the remaining seventeen colleges taken together.

It may be added that several colleges, *e.g.* Lincoln, Keble, Oriel and Pembroke, unless our authority misleads us, offer no encouragement to mathematics, but one of these, Keble, offers a science scholarship.

Turning to Cambridge, we find, as was to be expected, that most of the colleges offer awards for science; still, even at Cambridge four colleges out of seventeen, or nearly 25 per cent., viz. Corpus Christi, Magdalene, Queens' and St. Catherine's, exclude this branch. Owing to the Cambridge custom not to allot scholarships to definite subjects in advance, it is impossible to put forward such particulars as are given above for the sister university. But it may be taken that at Cambridge, as a rule, science receives more favourable treatment than at Oxford. Still, even at Cambridge in certain years not long past, as has previously been shown in these columns, the treatment accorded to science has seemed wanting in liberality, as, for example, in December 1898, when, out of one hundred and one scholarships (value 5150*l.*) given by ten colleges, only sixteen (value 745*l.*) were awarded to science candidates.

Returning now for a moment to the "School Calendar," which has afforded us the above information, it seems, so

far as we can judge, to be a really useful compilation. It gives great masses of very varied data about all sorts of examinations; contains an excellent "Calendar of Examinations" and much general information such as masters and their pupils need, and it is provided with a useful index.

THE ROYAL SOCIETY CONVERSAZIONE.

A LARGE number of exhibits of scientific interest were on view at the conversazione of the Royal Society, held on Wednesday of last week. Following our usual course, we give a list and brief descriptions of the objects exhibited, abridged from the official catalogue:—

The Badische Anilin and Soda Fabrik, Ludwigshafen on the Rhine, had an exhibit of synthetic indigo, consisting of (*a*) specimens of the raw material (naphthalene) and the intermediate products formed in the manufacture of synthetic indigo, as well as of the latter in four different forms; (*b*) examples of various textile materials illustrating the application of synthetic indigo on loose wool, slubbing, military cloths of different nations, cops, cross-reeled bundles, cotton piece goods both dyed and printed.

Mr. R. L. Mond and Dr. M. Wilderman exhibited a new and improved type of chronograph, in which, instead of moving the heavy drum, the clock moves a very light spindle carrying the writing pen round the drum.

Dr. J. Mackenzie Davidson showed (1) stereoscopic X-ray transparencies and negatives in a Wheatstone stereoscope and in a revolving stereoscope; (2) X-ray photographs of a bullet fired from a revolver. Dr. Davidson also demonstrated that if an ordinary photographic plate be exposed to X-rays and then to ordinary diffused actinic light, a reversed negative is obtained on development in bright white light.

An improved form of Thomson coal-calorimeter was exhibited by Mr. W. Rosenhain.

Apparatus for natural colour photography, and examples of its applications, were shown by Messrs. Sanger Shepherd and Co., who also exhibited a new camera for securing the three negatives through one lens at one exposure, and a camera for photomicrographic work fitted with colour filters for natural colour photography.

By means of a three-circle goniometer exhibited by Mr. G. F. Herbert Smith, the determination of the symmetry and the interfacial angles of crystals is considerably simplified; the crystal needs to be only once adjusted for the whole series of observations. By means of the particular optical arrangements in this instrument, measurements may be made through more than 180° across the end of the crystal by rotation of the horizontal circle only.

The Department of Applied Mathematics, University College, London, showed (1) a curve-adder, made by G. Coradi, of Zürich, for Prof. K. Pearson, F.R.S.; (2) lecture models, illustrating graphical treatment of girder-deflections; (3) a circular slide rule and planosphere, made about 1670, the former on Oughtred's system; (4) a slide rule, designed by Prof. de Morgan, and believed by him to be first circular slide rule.

Notabilia of Gilbert of Colchester were exhibited by Prof. S. P. Thompson, F.R.S.

Prof. G. Forbes, F.R.S., showed his folding range-finder, which has already been described in these columns.

Mr. J. Stanley Gardiner showed photographs of natives of the Maldive Archipelago, and photographs of the coral reefs.

Coloured sketches of birds and fishes obtained during the voyage of the *Discovery* to New Zealand were exhibited by Mr. E. A. Wilson.

Mr. J. Gray exhibited cephalometric instruments and cephalograms specially designed for measuring and taking contours of the living head.

The director of the British Museum (Natural History) showed (1) models of deep-sea fishes (*Gastrostomus bairdi* and *Saccopharynx flagellum*); (2) three statuettes of horses and one of a Hungarian bull, one-fourth natural size, by G. Vastagh, of Buda-Pesth. These were exhibited with a view to direct attention to the desirability of having similar models made of the British breeds of horses and cattle.

Newly discovered fossil mammals and reptiles from Egypt were also exhibited by the director of the British Museum (Natural History). The principal mammalian remains exhibited were those of Mœritherium and Palæomastodon, from the Upper Eocene and Oligocene respectively, which seem to be the oldest known ancestral Proboscidea. Mœritherium is a comparatively small animal, still retaining the canines and all the incisor teeth in the upper jaw, though the second pair of incisors is much enlarged. Palæomastodon has nearly reached the stage of dentition known in Mastodon, but more teeth are simultaneously in use, and the third molar is simpler than in the latter. Barytherium, represented by a mandible and part of the upper jaw, is a large and massive animal of uncertain affinities. The vertebræ named Gigantophis indicate the largest known snake, probably 50 feet in length.

On behalf of Colonel Sir Edmund Antrobus, Bart., Mr. W. Gowland showed a number of stone implements, &c., from Stonehenge.

On behalf of Miss Breton, the Rev. H. H. Winwood showed some striking water-colour sketches, executed by her, of cañons, glaciers and waterfalls in the United States and British Columbia, illustrating effects of various agents in land-sculpture.

Mr. T. Andrews, F.R.S., exhibited photomicrographs of the crystalline structure of platinum and of the crystalline structure of large steel ingots. Prof. A. H. Church, F.R.S., showed series of zircons from Ceylon, illustrating range of density and colour. Dr. C. A. MacMunn showed (1) the spectrum of a zircon; and (2) spongioporphyrin, the colouring matter of *Suberites Wilsoni*, an Australian sponge. This name has been given by Prof. Ray Lankester to the above pigment. The pigment gives a very remarkable absorption spectrum, recalling to mind that of oxyhæmoglobin, of turacin, of carminic acid, &c.

Some successful attempts to reproduce polarisation effects by three-colour printing were shown by Prof. H. A. Miers, F.R.S. The pictures were collotype prints from photographs of the coloured interference figures produced by crystal sections in a polariscope.

The experiments shown by Prof. J. A. Fleming, F.R.S., to illustrate the effect of ultra-violet light on the electric discharge attracted much attention. Effects of ultra-violet radiation were also shown by Dr. Dawson Turner.

Sir Norman Lockyer, K.C.B., F.R.S., showed (1) metallic spark spectra in air and water. Photographs of spark discharges from poles of iron, magnesium, zinc and copper showing (*a*) broadened bright lines, (*b*) broadened bright lines with central absorption, and (*c*) broadened bright lines with non-symmetrical absorption (maximum of emission towards red); (2) spectra of meteorites on silver poles, showing the varying intensity of lines due to special constituents; (3) spectra of rocks and minerals on silver poles, showing distribution of vanadium, titanium, chromium, &c.; (4) spectra of plant ashes on silver poles.

A new temperature indicator (Whipple's) was shown by the Cambridge Scientific Instrument Company. This instrument is intended for use with a platinum resistance thermometer. The bridge-wire is wound on a cylinder in the form of a screw, and the sliding contact is moved until the resistance of the thermometer is balanced.

Mr. C. E. Stromeyer gave an experimental illustration of one cause of steam-pipe explosions.

A new and very effective electrical influence machine suitable for campaign work with Röntgen rays was shown by Mr. W. R. Pidgeon.

One of the most novel exhibits was a large prism of vitreous silica shown by Mr. W. A. Shenstone, F.R.S., and Mr. J. W. Gifford. The employment of vitreous silica in optical work has been delayed by the impossibility of building up very large and perfectly homogeneous masses of the material in the oxy-hydrogen flame. But this difficulty has now been overcome to a great extent.

Prof. Wyndham R. Dunstan, F.R.S., director of the scientific department of the Imperial Institute, exhibited (1) poisonous fodder-plants and food-grains, and their cyanogenetic glucosides. These illustrate an investigation of the cause of the hitherto obscure poisonous action of certain Indian and Colonial fodder-plants and food-grains. The plants shown have now been proved to furnish prussic (hydrocyanic) acid, and in the cases of

Lotus arabicus and *Sorghum vulgare* the poison has been shown to have its origin in cyanogenetic glucosides, which occur in the young plant, but gradually disappear as the seeds ripen; (2) Indian and Egyptian drugs and their constituents. (*a*) *Hyoscyamus Muticus* and *Hyoscyamine*. This remarkable plant, probably the "nepenthe" of Homer, grows both in India and Egypt, and has been long known as a constituent of narcotics under the name of "bheng" or "bhang." It has been found to contain the alkaloid, hyoscyamine, in larger proportion than any other known plant. As the plant is abundant in Egypt it is now being exported for the manufacture of this alkaloid, which is used medicinally It grows abundantly in the sand of the desert, which analysis shows to be nearly free from nitrogenous compounds. The manner in which the plant obtains its nitrogen is being investigated. (*b*) Indian Aconites and their poisonous alkaloids. (3) India-rubber from Bahr el Ghazal and Zululand. Varieties of gutta-percha from Sarawak, Ceylon and West Africa; (4) coal, iron ores, mica, and other minerals from India, British Central Africa, Nigeria, Somaliland, Trinidad, and the Grecian Archipelago; (5) specimens of tobacco cultivated in Bermuda, with photographs of the crops; (6) specimens of Indian and Australian gums and resins. (*a*) *Cochlospermum gossypium* (India) and *Sterculia acerifolia* (Australia). These gums possess the peculiarity of generating acetic acid when exposed to the air. (*b*) *Callitris verrucosa* (Australia). This resin is remarkable in containing a volatile resin. The resin resembles sandarac in its properties, and is likely to be of commercial value.

Mr. W. M. Mordey and Mr. G. L. Fricker showed an electricity meter invented by them, and intended especially for consumers having a comparatively small number of lamps. It consists of an ordinary clock, deprived of its hair-spring, and carrying a few pieces of iron wire or strip on its balance wheel. This balance wheel is surrounded by a coil of wire conveying the current to be measured. With this arrangement the oscillations of the balance wheel are directly proportional to the current through the coil, with either direct or alternate current. The clock therefore goes at a speed proportional to the current, but does not go at all when there is no current. Geared to the clock is a counter which records the ampere-hours or (on constant pressure circuits) the kilowatt-hours or Board of Trade units.

Prof. W. Ramsay, F.R.S., had an exhibit to illustrate that many persons see the colour of a vacuum tube containing krypton as lilac, many as green. The phenomenon appears to be conditioned by the size of the yellow spot on the retina.

Film structures in metals and other plastic solids were shown by Mr. George Beilby. Metal surfaces are covered with a transparent lacquer-like film of their own substance. This covering film is formed by the welding together of minute reflecting films or "spicules." Spicules are visible in all metal surfaces, but are specially well seen in surfaces which have been frosted by the action of heat and chemical reagents. When the rounded end of a burnisher is drawn across a frosted surface, the separate films are welded into a transparent continuous film.

Prof. A. Schuster, F.R.S., exhibited (1) the spectrum of iron in the flame of the Bunsen burner; (2) a Rowland grating of one metre focus.

The scales of fishes as an index of age was the subject of an exhibit by the Marine Biological Association. The scales of many fishes show a series of parallel eccentric lines, which indicate successive increments of growth. These lines of growth have been found to be more widely separated in that part of the scale formed during the warm season of the year than in the portion formed during the cold season. The alternation of the two series gives rise to the appearance of "annual rings," which indicate the age of the fish in years. The markings are subject to individual variation, and Mr. J. Stuart Thomson has been engaged on their investigation in fish of different species captured at all seasons of the year. His results show that it is possible to determine the age of individual fishes of many species with considerable precision—a conclusion which will greatly facilitate the study of other points in the natural history of fishes, and has important practical applications.

Mr. A. C. Cossor showed (1) a "Braun" tube for kathode rays; (2) a new therapeutic X-ray tube. The object of the "Braun" tube is to permit of a wide range in the different experiments that can be made, showing the action of magnetic disturbances on the kathode rays. In this tube these magnetic effects are delicately and precisely shown.

Mr. J. E. Stead's exhibit consisted of (1) micro-structure of iron, and meteoric irons containing free phosphides and carbides of iron and nickel; (2) the micro-constituents of steel.

The Cambridge Observatory exhibited diagrams referring to preliminary results of the solar parallax, from observations of the planet Eros.

The Royal Astronomical Society showed photographs of the nebula surrounding Nova Persei, photographed by Mr. G. W. Ritchey, Yerkes Observatory, U.S.A.

Manuscripts relating to the discovery of Neptune, by the late Prof. J. Couch Adams, F.R.S., were shown by St. John's College, Cambridge, through Prof. R. A. Sampson. The manuscripts date from 1841, when, as an undergraduate in his second year, Adams first determined to attack the problem, to 1846, when the planet was discovered. In all, Adams made no less than six separate solutions of the problem, similar in method but largely independent, each advancing in some particular upon the last. Of these the earliest, though necessarily the least perfect, is perhaps of most interest. It was completed at the end of September, 1843, three years before the planet was observed with the telescope. The position assigned to Neptune by this first determination was some 18° from the truth. The solution dated April 28, 1845, departs from the subsequently observed position by 3°; that of September 18 and October of the same year by less than 1°; that of August, 1846, by about $1\frac{1}{2}°$.

Mr. A. Vernon Harcourt, F.R.S., showed an apparatus for the regulated administration of chloroform.

Mr. J. E. Petavel and Captain J. Bruce-Kingsmill exhibited (1) a recording pressure gauge for artillery; (2) a recording pressure gauge for low-pressure explosions (suitable for gas-engine research and experimental physics), shown by Mr J. E. Petavel. A description of the apparatus will be found in the current number of the *Philosophical Magazine*.

The National Physical Laboratory showed a plane mirror, given to the Laboratory by Dr. Common, F.R.S.

Living specimens of ovivorous parasites (Mymaridæ), together with larvæ and pupæ in the eggs of Liburnia (frog-hoppers), were shown by Mr. F. Enock.

Mr. W. E. Hoyle showed luminous organs in *Pterygioteuthis margaritifera*, a Mediterranean Cephalopod. The most striking feature of these organs is that they are concealed by the integument, and are only effective by reason of its transparence in the living condition.

Lieut.-Colonel Bruce, F.R.S., exhibited *Trypanosoma Theileri*, a new species of parasite discovered in the blood of cattle in South Africa. This new Trypanosoma was lately discovered by Dr. A. Theiler, who is in charge of the bacteriological laboratory of medical officer of health, Pretoria, Transvaal. The species can be at once distinguished from the Trypanosomas of Surra, tse-tse fly disease, or rat by its larger size, it being almost twice as large as any of the others. In general appearance it conforms closely to the others in possessing an oval protoplasmic body, a longitudinal fin-like membrane and a single flagellum. It only infects cattle. Horses, dogs, goats, rabbits and guinea-pigs are all immune, neither showing symptoms nor the presence of the parasites in the blood.

A specimen of a Trypanosoma found in the blood of man was shown by Mr. J. Everett Dutton on behalf of the School of Tropical Medical, Liverpool. The Trypanosoma was first discovered in the blood of a European in Government employ at Bathurst, West Africa. The presence of the parasite was associated with symptoms closely resembling those occurring in animals suffering from tse-tse fly disease. The parasite was again found in a preparation of blood taken from a native child at Bathurst (see p. 15).

Messrs. R. and J. Beck, Ltd., exhibited the "Imperial" microscope with mechanical adjustments for critical work, showing Grayson's micrometer rulings in realgar up to 60,000 lines to the inch.

A collection of ear-rings from British New Guinea was shown by Dr. A. C. Haddon, F.R.S.

Microscopic preparations of *Astrosclera Willeyana*, with specimens illustrating the determination of the mineral constituent of the skeleton by Meigen's method, were shown by Mr. J. J. Lister, F.R.S., and Mr. A. Hutchinson. Astrosclera was first collected by Dr. A. Willey in the Loyalty Islands, and has since been obtained at Funafuti in the Ellice group. It is regarded as the type of a distinct division of sponges, and differs from other known calcareous sponges in the structure of the soft

tissues and the skeleton, and in the fact that the mineral constituent of the latter is not in the form of calcite.

Mr. E. T. Newton, F.R.S., showed a series of otoliths, chiefly of living British fishes, both marine and freshwater, showing the various forms assumed in the different genera.

Prof. W. K. Huntington exhibited (1) a tilting stage for the microscope; (2) optical bench for metallurgical work.

Dr. A. Muirhead gave a demonstration of retransmission on submarine telegraph cables (cable relaying).

Kite and winding-in apparatus for raising meteorological instruments was shown by Mr. W. H. Dines.

The distribution of electric currents induced in a solid iron cylinder when rotated in a magnetic field was shown by Prof. E. Wilson.

During the evening, demonstrations, by means of the electric lantern, were given in the meeting room by Sir Henry Trueman Wood, on the application of photography to the production of pictures in colour, and Dr. R. D. Roberts, on lantern slides in natural colours of the Grand Cañon of the Colorado, the Sierra Nevada, California and the Yellowstone Park.

NOTES.

THE *London Gazette* announces that Sir William Turner Thistleton-Dyer, K.C.M.G., C.I.E., F.R.S., Director of the Royal Botanic Gardens, Kew, has been appointed Botanical Adviser to the Secretary of State for the Colonies.

DURING the first half of this month the weather over this country was very abnormal for the season. The reports issued by the Meteorological Office show that in the early part of the month a decided depression approached from the north-west, the centre advancing over Scotland, travelling to the south-east, and causing thunderstorms and hail in many places. The subsequent distribution of pressure, which was relatively high off our south-west coasts and over north and south-west Europe, while depressions lay in various parts of the intervening regions, occasioned persistent inclement northerly and north-easterly winds. These continued with little variation until May 14, by which time a great change occurred in the type of pressure, under the influence of which westerly winds and some rise of temperature subsequently occurred, but heavy and sudden downpours of rain continued between the bright intervals. For any comparison of the persistent cold spell it is necessary to go back to the year 1879, when, during the first half of May, the mean of the daily shade maxima at Greenwich was approximately 54° and the minima 36°, against 53° and 37° in the corresponding period of this year. The maximum shade temperature on any day has not exceeded 57°·3, but in 1879 the maximum temperature exceeded 60° on three occasions and reached 66°·2 on May 5. On the night of the 13–14th, the exposed thermometer on the grass registered 22°·6 in the neighbourhood of London, and the maximum of the previous day was about 14° below the normal, while in May 1879 the lowest grass temperature was 24°·6. An examination of the Greenwich records since 1840 shows that there has been no year, except the present, in which the shade temperature has not reached 60° during the first half of May.

IN NATURE of February 20 (vol. lxv. p. 367), Mr. A. B. MacDowall pointed out that the Greenwich observations of the last thirteen years favour a connection between thunderstorms and the lunar phases, as has been found for other places. Investigation of the meteorological records of several observatories show that a larger percentage of thunderstorms occur about the time of new moon than about full moon, and in the two earlier phases than in the two later. M. V. Ventosa writes from the Madrid Observatory to say that he has obtained similar evidence of this relationship from an examination of observations made at that Observatory in the twenty years 1882–1901. Classified in four groups about four lunar phases, the results are as follows:—

	New Moon.	First Quarter.	Full Moon.	Last Quarter.
Thunderstorms ...	132 ...	104 ...	99 ...	120
Percentage ...	29·0 ...	22·8 ...	21·8 ...	26·4

Mr. MacDowall, to whom we have shown M. Ventosa's letter, remarks:—"The results are an interesting extension of the subject. While at none of the stations which have thus been compared are the differences between those weekly percentage numbers large, the general agreement, in showing, especially, more thunderstorms about new moon than about full moon seems remarkable, and may (I also hope) incite to further inquiries in the same direction, where the requisite data are available."

SEVERAL correspondents have sent us references to observations of peculiar lunar halos such as that described by Prof. Barnard in our issue of May 1 (p. 5). The singularity consisted in the moon being in the centre of one halo and on the circumference of another at the same time. Mr. H. W. Croome Smith directs our attention to a similar appearance observed on February 28, 1890, and described in the *Bristol Times and Mirror* of the following day. The moon was then nine days old, so that the conditions were very similar to those existing at the time of Prof. Barnard's observation.

THE last Report of Mr. W. Bell Dawson, C.E., on the survey of the tides and currents in Canadian waters contains an interesting account of the work that is being carried on in obtaining data as to the tides in the St. Lawrence and in the Bay of Fundy, and in the preparation of trustworthy tide-tables for Halifax, Quebec, St. John's and British Columbia. The part of the Report of most general interest is that relating to the tides in the Bay of Fundy. Further observations which have been obtained during the past year confirm the statement previously made by Mr. Dawson that the range of these tides has been greatly exaggerated. The range of spring tides in Noel Bay when they are at a maximum is 50½ feet and 43½ feet at neaps; at Horton Bluff, 48 feet and 40 feet; at Cumberland Basin, 45¼ feet and 38 feet. The difference between the level of the highest known tide, the "Saxby tide" of 1869, and the lowest point to which the water has been known to ebb out is 53 feet. The rise of this tide above mean sea-level was 29·24 feet, and the level of the lowest known low water below mean sea-level was 23·76 feet. The record tide of 1869 rose from 2 to 3 feet above the banks which protect the enclosed marshes and flooded the country.

IN our issue of February 13 (vol. lxv. p. 350), two new forms of electric resistance furnace suitable for laboratory work were noticed. The *Zeits. f. Elektrochemie* of April 3 contains details of a research carried out by Herr W. C. Heraeus with a modified form of this furnace relating to the melting point of manganese. The coil of platinum wire was replaced by a strip of very thin foil, wound spirally round the porcelain tube. A temperature of 1300° C. could be attained in three minutes with a tube 16 mm. in diameter having a spiral 15 cm. in length wrapped upon it, and by careful attention to the resistance, temperatures could be observed to within 5° C. of absolute accuracy. The tube employed in the observation of the melting point of manganese was provided with an alumina boat to carry the small piece of metal used for the determinations—with rubber connections by which hydrogen gas was passed through the tube during the observation—and with a small telescope by means of which the exact moment of melting could be noted. A Chatelier thermo-element was used for recording the temperatures. The mean of six determinations gave 1245° C. as the melting point of the metal. Attempts to use nitrogen and carbonic acid gas in place of hydrogen failed, since the former gas yielded a nitride with the manganese and the carbonic acid gas dissociated at 1000° C. The reducing action of the hydrogen

gas at the high temperature also caused difficulties with the thermocouple, and many determinations failed owing to the brittleness produced at the point of contact of the two metals.

PROF. H. A. MIERS, who paid a visit in 1901 to the Yukon gold-fields, has published a brief account of his observations, in a letter addressed to the Hon. Clifford Sifton, Minister of the Interior, Ottawa. His principal object was to study the mining methods and the auriferous deposits of the Klondike district. He describes the various methods of thawing the frozen gravel, the latest process being the forcing of water into the ground by means of a pulsometer pump. While admitting the enormous wealth of the district, he points out that it is ceasing to be a poor man's camp, and requires extensive capital and labour for its development. The failures connected with English capital have been disastrous, not necessarily on account of any want of judgment in selecting claims, but mainly because the representatives of English companies "in many cases lacked the judgment and the stability of character which were needed, or had not the interests of their employers sufficiently at heart." At present a comparatively small portion of even the Klondike district has been worked out, while the Yukon territory is auriferous over considerable areas and has been very imperfectly prospected. Moreover, there is nothing to indicate that the gravels and the gold which they contain have been transported any considerable distance, or have been derived from any rocks which differ from those now found in the district. The search for auriferous quartz is therefore hopeful.

THE Summary Report of the Geological Survey of Canada for 1901 (Ottawa, 1902, price 25 cents) extends to 269 pages, being considerably larger than previous reports. This increase has been made by the director, Dr. Robert Bell, in response to the general desire for early information on all points which may be of immediate value to the public. Prominence is therefore given to observations and discoveries which may have an economic bearing. Moreover, the amount of work recorded in this report is believed to have far exceeded that of any previous year. No less than thirty-one parties were engaged in explorations, including those conducted by a number of competent geologists, principally college professors, whose temporary services were secured during the summer season. Dr. Bell contributes an interesting statement on the aims and methods of the work in the field and at headquarters; and the reports of the members of the staff are published under their own names. The Yukon district naturally occupied attention, and mention is made of the occurrence of dendritic gold on a boulder found in one of the creeks, a fact which serves to show that some of the gold has been deposited from solution. Examinations have been made of the Cretaceous coal-fields of Crow's Nest Pass, where there is a vast amount of workable coal of excellent quality; of the oil-fields of Lambton county, Ontario, and of Westmoreland county, New Brunswick; of the natural gas in Essex and Welland counties; and of the Carboniferous Coal-measures of New Brunswick, in which water-worn coal-pebbles have been noticed. In an account of the Cambrian rocks and fossils of Cape Breton, reference is made to the solitary character of the Ostracods, which in other formations occur in profusion. Some remains of Trionyx from the Cretaceous rocks of Alberta are described and figured. The glacial origin of cirques or corries and of certain mountain tarns in western Canada is pointed out; and many other topics of general interest are dealt with in the various reports, such as agriculture, including fruit farming, water supply, &c. The occurrence of the mineral faujasite is mentioned as new to Canada.

IN the Report of the Selborne Society for 1901–2, the council emphasises the need of new members in order that the work of the association may be carried on with efficiency.

IN No. 1266 of the *Proceedings* of the U.S. National Museum, Messrs. Jordan and Snyder continue their account of the fishes of Japan, dealing in this instance with the wrasses and their allies. Several new forms are described.

JUDGING by the enlarged size of the April number, the Australian ornithological journal, *The Emu*, appears to be gaining a well-deserved popularity. Among the contents of this issue are a paper on various Tasmanian birds, by Colonel Legge, and a continuation of Mr. D. le Souëf's notes on protective coloration in Australian birds and their nests. Of several excellent illustrations, a group of gannets nesting calls for especial commendation.

A MOST remarkable instance of collateral budding in two annelids belonging to the genus Trypanosyllis is described by Dr. H. P. Johnson in the *American Naturalist* for April. Both species are inhabitants of the Pacific coast of America; and the sexual "zooids" they produce by this peculiar mode of budding are very numerous, and, with the parent animal, look like a bunch of fern-leaves. The most remarkable feature about the phenomenon is that the full-grown and detached zooids, although provided with generative organs, entirely lack any functional structures for alimentation. "The zooid is, therefore," as the author remarks, "as incapable of leading a prolonged independent existence as the famed palolo of the South Seas. It is no more than a living engine for the dissemination of the genital products which it carries, and that duty must be accomplished solely by the expenditure of the stored up energy which it had derived from the stock." Other members of the family are known to produce zooids by linear budding; but in this case the zooids are provided with digestive organs. The zooids of Trypanosyllis are regarded as an extreme specialisation of those of the linear type. But there is another curious circumstance. In the group producing zooids by linear budding the adult stock is sessile, or nearly so, and the object of having freely moving zooids is therefore apparent. But in Trypanosyllis the adult stock is not fixed; and the reason for the development of zooids thus remains to be discovered.

THE Austrian Meteorological Office (Dr. J. M. Pernter, director) has published its *Jahrbuch* for 1900. This valuable series of observations has been issued in practically the same form for thirty-seven years; the present volume contains monthly and yearly results at more than 400 stations, and daily observations at twenty-two stations, including, among a few foreign places, Port-au-Prince (Haiti) and Jerusalem. An interesting feature of this laborious compilation is the reduction and publication of the results obtained from the autographic records of several mountain observatories, including the Sonnblick (3106 metres), Obir (2144 metres) and Berghaus (2044 metres). Dr. M. Margules contributes a detailed discussion of the barometric pressure and wind conditions based on the results of a number of stations in Lower Austria.

DR. P. POLIS, superintendent of the Meteorological Observatory at Aix-la-Chapelle has contributed to the April number of the *Meteorologische Zeitschrift* an interesting paper on the daily period of rainfall. The paper is based chiefly on very careful observations at his own station, and the results have been compared with those obtained at several other European observatories. We can only refer to a few of the conclusions arrived at. He finds that (1) in northern and central Europe the summer and winter seasons have opposite daily periods. In summer the heaviest falls occur in the afternoon, and the lightest near noon and midnight. In winter the maximum occurs from 8h. to 10h. a.m. and from 4h. to 8h. p.m. (2) Maritime climates have a more marked daily period in the winter season, and continental climates in the summer season. (3) At his own

station the maximum amount in spring falls between 6h. and 8h. p.m., while the greatest frequency occurs between 8h. and 10h. a.m.; in summer the maximum amount occurs between 2h. and 8h. p.m., and the greatest frequency between 2h. and 4h. p.m. In winter there are two maxima of quantity, 8h. to 10h. a.m. and 6h. to 8h. p.m., while the time of greatest frequency coincides with first period.

"SOLOID" microscopic stains prepared by Messrs. Burroughs, Wellcome and Co. are aniline and other dyes in a tabloid form easily dissolved in water or alcohol or both, as the case may require, and therefore most useful. They are easily preserved, always ready and portable. The list at present published includes a great variety of the most generally used dyes, as hæmatoxylin, eosin, eosin and methylenblue, fuchsin, gentian violet, thionine blue, &c. While admitting, from direct tests made with some of these soloids, their usefulness, it should not be forgotten that, like other short cuts, also the "Soloid" short cut should only supply a necessity, but should not, and cannot, supplant the recognised laboratory methods. The dye marked "Louis Jenner stain" (eosin and methylenblue) is a good eosin but a bad methylenblue stain, and cannot for a moment compare with Czinzinski's solution (eosin and methylblue.) Pages 3 and 4 of the leaflet issued with the soloids, containing descriptions of methods of staining bacilli and blood, may be safely omitted.

IN a series of five papers published during the last few months in the *Journal of Physiology*, Dr. H. M. Vernon has described numerous observations on the zymogens and enzymes of the pancreas. The method used for estimating the tryptic power of extracts depends on the digestion of measured quantities of finely chopped fibrin in small graduated centrifugal tubes. The process is completed in about half an hour, and the average error of experiment is only 5 to 10 per cent. The necessity of adopting a rapid digestion method is shown by the fact, hitherto not adequately recognised, that the tryptic ferment is an extraordinarily unstable body. Thus 70 to 80 per cent. of the ferment in a very active extract may be destroyed in an hour by ·4 per cent. Na_2CO_3 at 38°. If such extracts be kept for weeks they gradually deteriorate in activity, and the trypsin still remaining undestroyed is found to be a more and more stable body, till finally the last portions of the ferment left may be ten or twenty times more stable than the first. It was accordingly concluded that trypsin is not a single substance, but that there must exist series of trypsins of varying degrees of stability. There are likewise series of rennins, but not of diastases, though is was shown that the diastatic ferments of the pancreas, of saliva and of malt differ from each other considerably in their hydrolysing action on starch. As regards the zymogens, it was found that the rennet ferment has a zymogen very similar to that of the tryptic ferment, whilst the zymogen of the diastatic ferment is an insoluble body. The most energetic agent in the conversion of tryptic zymogen into enzyme was found to be active enzyme itself. Thus if even 1 per cent. of an active extract were added to a solution of zymogen at 38°, it might convert a third of it into enzyme in an hour. Curiously, the rennet ferment was likewise liberated from its zymogen by the tryptic ferment, and not by the rennetic.

MESSRS. BLACKIE AND SON have commenced the issue of a cheap edition of Kerner and Oliver's "Natural History of Plants," which is well known to all students of plant life. The work will be published in sixteen monthly parts at eighteen pence each, and is thus brought within the means of everyone who is interested in the study of botany. Used either as a guide or a reference book, the work is appreciated by all who know it, and it deserves a sphere of influence even greater than that it already possesses.

WE are glad to learn, from the *Bulletin* of the St. Petersburg Society of Naturalists, that the herbarium of "Flora Rossica," which was begun by the late M. S. I. Korzinsky, member of the St. Petersburg Academy of Sciences, continues to be issued by the Academy under the supervision of M. D. I. Litwinow. Six more fascicules (xiii.–xviii.) appeared lately, together with one fascicule of "Schedæ Herbarium Floræ Rossicæ." We also learn from the same source that M. P. V. Syuzev has undertaken the publication of a "Flora Uralensis exsiccata." This herbarium will comprise chiefly the flora of the province of Perm, but also of Ufa and Orenburg.

A WORK on "The Narym Region," by M. A. Th. Plotnikoff (*Memoirs* of the Russian Geographical Society, Statistics, vol. x. St. Petersburg, 1901), contains a valuable description of a very interesting portion of the province of Tomsk, namely, the portion on the water-divide between the Ob and the Irtysh, as also on the rivers Ket, Parabel and Vas'yugan, which represents mostly an immense marsh—to a great extent a lake during the period of high water in the rivers—and the surface of which is covered with a floating carpet of decayed grass and knolls of ground upon which low bushes of birch will grow. A general description of this wide region (about 100,000 sq. miles) and of its nearly 8000 inhabitants—Russians, Ostyaks and Ostyak-Samoyedes—is given by the author, who has for several years resided at Narym.

ABOUT seventeen years ago, Prof. Salvatore Sardo extracted from the siliquæ of *Bignonia Catalpa* an acid which he called catalpic acid, and to which he assigned the formula $C_{14}H_{14}O_6$. A reinvestigation of the products of the Catalpa fruit has now been made by Signor A. Piutti and Dr. E. Comanducci, whose results are described in the *Rendiconto* of the Naples Academy, viii. 3, Instead, however, of obtaining an acid with the formula assigned by Sardo, they obtained from the immature pods a substance corresponding to the formula $C_7H_6O_3$, which is shown by numerous evidence to be identical with *p*-oxybenzoic acid. In addition they have extracted what appears to be a combination of paroxybenzoic acid and protocatechuic acid, previously obtained in other ways by Hlasiwetz and Barth, having the formula $C_7H_6O_3$, $C_7H_6O_4 + 2H_2O$, but the attempt to separate the two acids has hitherto ended in negative results, although the other acid appears to have been isolated by Eykman from the fruits of *Illicium religiosum*. Many questions suggest themselves as to the state in which these acids occur in the Catalpa fruit, and whether they are free or in combination, and it is proposed to collect a quantity of the fruits for further observation.

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Sir William Hoste; a Mozambique Monkey (*Cercopithecus pygerythrus*) from East Africa, presented by Mr. J. Bolt; a Common Viper (*Vipera berus*) European, presented by Mr. C. Spencer Bubb; a Hartebeest (*Bubalis*, sp. inc.) from Angola, purchased; two Japanese Deer (*Cervus sika*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SATURN VISIBLE THROUGH THE CASSINI DIVISION.—An interesting circular has been issued by Mr. C. T. Whitmell, of Leeds, calling attention to the possibility of this phenomenon being observed. On July 17, 1902, at 13h. G.M.T., Saturn will be in opposition to the sun, and about 7h. G.M.T. on that day the earth and sun will be equally elevated above the ring plane, their Saturnicentric declination being about 22° 26′ 17″ N. Adopting Prof. Barnard's estimate of 2270 miles for the breadth of the Cassini division, and fifty miles for the thickness of the rings, Mr. Whitmell calculates that the effective opening of the division will be 820 miles, corresponding to 0″·20 in angular

measure at the earth's distance. Under these conditions a line from the sun to the earth will pass through the rift in the rings to the planet, and a terrestrial observer, suitably placed, may be able to view through the rift a portion of the planet's surface lit up by the sunlight. The effect will be that, of the arc of the Cassini division crossing the planet, a small portion will appear bright instead of dark, and may almost disappear; as the albedo of Saturn is less than that of the adjacent portions of rings A and B, however, it is likely that there will be sufficient contrast to show the phenomenon.

There appears to be no record of any previous observation of this kind, and it will obviously be one of great delicacy and difficulty. As the exact limits of time and place are not absolutely determinable, it is hoped that the planet will be watched for some time before the date given.

CATALOGUE OF NORTH POLAR STARS.—Prof. Pickering has issued a catalogue of 589 stars in the vicinity of the North Pole as a separate part, No. 1., of vol. xlviii. of the *Annals of the Harvard College Observatory*. The measures are from enlargements made from the central portions of four negatives obtained with the 11-inch Draper telescope on November 29, 1887, February 23, 24 and March 10, 1897, with exposures of 60, 120, 120 and 101 minutes respectively. Full details are given of the reductions employed, and in consequence of the arrangements made at the Astrophotographic Congress of 1900, the positions are published in rectangular coordinates, which plan is to be adopted in general for future issues.

THERMAL EXPANSIONS AT LOW TEMPERATURES.[1]

THE apparent specific gravities of boiling liquid oxygen which resulted from weighing in the liquid a series of metals and other substances were given in a lecture entitled "New Researches on Liquid Air," printed in the Royal Institution *Proceedings* for 1896. For instance, silver, calc spar, rock crystal and iodide of silver gave the respective apparent densities 1·1278, 1·1352, 1·1316 and 1·1372. On correcting the weight of liquid displaced by each substance for contraction to $-182^\circ{\cdot}6$—by calculating a Fizeau mean coefficient of expansion for the range of temperature employed, on the assumption that the parabolic formula might be legitimately extended to low temperatures—it was found that the real density of liquid oxygen so deduced for all the bodies used was, as a mean, 1·137.

The determination of the densities of substances at the temperature of the boiling point of oxygen—and hence of their mean coefficients of expansion between that temperature and ordinary temperatures—opens out a very large field of investigation, from which, if a sufficiently large number of observations were available, valuable deductions might be drawn. On account, however, of the expense and trouble of producing quantities of liquid oxygen, its use for this purpose is not likely to become general, although, when available, it is the easiest body to use in conducting such experiments, especially when the vacuum vessel containing it is immersed in a larger vessel containing the same fluid or well-evaporated air. The ease with which liquid air can now be obtained in many laboratories suggests that its application to work of this kind would in some cases be a convenience, and the present investigation was undertaken with the desire of ascertaining what accuracy could be attained, and how the method could be applied to inorganic or organic substances which occur in the form of fine crystals.

The use of a mixture of varying composition and density like liquid air necessitates a determination of its density with accuracy and rapidity before and during the course of the experiments. For this purpose, in the experiments about to be detailed, the liquid air that had been allowed to evaporate for twenty-four hours in advance was used in large silver-coated vacuum vessels of some 3 litres capacity. In order to ascertain the density of the liquid, a polished silver ball, which had been weighed once for all in liquid oxygen, was weighed in the sample of liquid air, and from the relative weights thus found the density of the liquid air could be approximately determined, assuming that of liquid oxygen to be 1·137.[2] To prevent any disturbing ebullition in the liquid-air flask in which the weighings took place, and to reduce the rate of its evaporation to a minimum during the course of an experiment, the substance to be used was previously cooled in a supplementary vessel containing liquid air and then transferred to the large flask. To avoid as far as possible the formation of cracks in the bodies during the process of immersion in the liquid air, it was found advisable to cool them slowly in the air of the vacuum flask first, and then to lower them into the liquid.

In this way, with proper care and attention, results were obtained comparable in accuracy with the density taken in liquid oxygen. Substances like solid carbonic acid and ice were weighed in the cool, gaseous air of the vacuum vessel, and their weights subsequently corrected for buoyancy. The temperature of the densest and lightest samples of liquid air was ascertained by the hydrogen thermometer, and that of the others deduced by graphic interpolation. As the entire range of temperature through which the bodies were cooled amounted to about 200°, a degree or two up or down has no real influence on the results; the extreme range of temperature in the air samples was from $83^\circ{\cdot}8$ to $86^\circ{\cdot}1$ Abs.

When the body to be examined was a salt, it was employed in the form of a compressed block. One experiment was, however, made in a section of a large crystal of chrome alum. The salt, previously reduced to a fine powder, was moistened with water and compressed in a cylindrical steel mould under great hydraulic pressure. During compression the saturated salt solution drained away, and finally a cylindrical block of some 50 grammes of the salt was obtained free from porosity and hard enough to allow its surface to be polished. In this form salts and other materials similarly treated are especially adapted for accurate specific gravity determinations. After such treatment it was found that all the mechanically attached water was got rid of in the case of hydrated salts, and also in such as did not combine with water. In order to get cylindrical blocks of the salts showing no porosity, the presence of water, or rather the saturated salt solution, was found to be essential during the application of pressure. In the same way it was found to be an advantage in compressing such a substance as solid carbonic acid to moisten it with a fluid like ether before applying the hydraulic pressure.

Recalling the work of Playfair and Joule,[1] which originated in a suggestion of Dalton's that the volume of a hydrated salt in solution was simply the volume of the water of crystallisation, ice and some hydrated salts were selected, as well as some other bodies the coefficients of expansion of which they had determined. Substances of special interest were included in the list, like mercury, sulphur, iodine and solid carbonic acid, the latter being particularly important as an example of a solidified gas.

In the further conduct of an experiment, the observations made on a substance were three, namely, (*a*) the weight in grammes of the substance and suspending platinum wire, either in air of about 17° C. temperature or in the gaseous air in the flask containing the liquid air; (*b*) the weight in grammes of the body and wire when immersed in the liquid air; and (*c*) the weight in grammes of the suspending platinum wire in ordinary (17°) air.

In the case of substances of less density than liquid air, a polished copper ball weighing about 38 grammes was used as a sinker.

Two experiments were made on compressed cylinders of solid carbonic acid. In the first of these the carbonic acid was compressed dry, in the second, after a few drops of ether were added. The specific gravities of solid mercury, iodine and sulphur were also determined in liquid air. The iodine was in the form of a compressed cylinder, but the sulphur was a piece of a crystalline mass of native origin.

The specific gravity of the actual portion of the substance weighed in the liquid air was, with one or two exceptions, determined also at the temperature of the laboratory, about 17° C. From the two sets of observations, the value of the mean coefficient of cubical expansion between 17° C. and the temperature of liquid air was calculated.

In calculating coefficients of expansion, various forms may be given to the formula employed, and correspondingly different results may be obtained from the same set of observations. For short ranges of temperature these results are practically identical, but this no longer holds for a range of temperature such as we

[1] "Coefficients of the Cubical Expansion of Ice, Hydrated Salts, Solid Carbonic Acid, and other Substances at Low Temperatures." By Prof. James Dewar, F.R.S. Abridged from a paper read before the Royal Society on May 1.

[2] As the correction due to the contraction of the silver ball between the temperature of boiling oxygen and that of the air sample is small, it may be neglected.

[1] "Researches on Atomic Volume and Specific Gravity" (*Chem. Soc. Journ.*, vol. i, 121).

have in these experiments. All that is possible in the present instance is to adopt a linear formula. The usual formula is $v_T = v_0 (1 + \alpha T)$, where the value v_0 at 0° C. becomes v_T at T° C. when α is the coefficient of expansion. If we use densities (d) instead of volumes (v) this formula becomes

$$d_0 = d_T(1 + \alpha T), \quad \text{or } \alpha = \frac{d_0 - d_T}{T d_T}; \quad \alpha = 0·000538.$$

Another formula, when T and T′ are the temperatures dealt with, is

$$d_T = d_{T'}\{1 + \alpha(T' - T)\}, \text{ or } \alpha = \frac{d_T - d_{T'}}{(T' - T)d_{T'}}; \quad \alpha = 0·000595.$$

Again

$$d_{T'} = d_T\{1 - \alpha(T' - T)\}, \text{ or } \alpha = \frac{d_T - d_{T'}}{(T' - T)d_T}; \quad \alpha = 0·000558.$$

Also we may choose a mean formula

$$\alpha = \frac{d_T - d_{T'}}{(T' - T)\frac{d_T + d_{T'}}{2}}; \quad \alpha = 0·000576.$$

The differences in the results of applying these formulæ are shown in the numerical values attached to each, which are calculated from the first experiment on solid carbonic acid, coupled with the specific gravity 1·53 of the solid at −78° C.

Perhaps as a matter of general convenience, the first of these formulæ is the best; however, the second was chosen to conform with the old work of Playfair and Joule, and it is the results of this formula which are mentioned below.

The temperature range is taken from about −186° C. to 17° C., unless otherwise stated.

Ice.—In determining the density at the temperature of liquid air of pieces of clear ice cut from large blocks, both the silver and copper balls already referred to were used as indicated. The true weight *in vacuo* of the silver ball was 132·2855 grammes, and that of the copper ball was 38·0802 grammes. The mean of the three densities obtained at −188°·7 C. is 0·92999.

Recently Vincent (*Roy. Soc. Proc.*, 1901) has redetermined the density of artificial ice at the freezing point, and also its coefficient of expansion. He finds the density to be 0·916, or from his tabulated results 0·91599. Playfair and Joule find the mean of the densities given by eight observers previous to them to be 0·919, and they themselves get 0·9184; Bunsen found it to be 0·9167. If we take this most recent determination, namely, 0·91599 at 0°, and 0·92999 at −188°·7, and use the formula

$$d_0 = d_T(1 + \alpha T)$$

we get $\alpha = 0·00008099$.

Vincent refers to "only one" estimate for natural ice, namely, 0·0001125, adding that "the mean of three available results for artificial ice is 0·000160"; finally, he gives the mean of four determinations of his own, namely, 0·000152. Apparently, then, we may take 0·0001551 as the mean coefficient of expansion of ice between 0° and (say) −20° C. Thus the mean coefficient of expansion between 0° and −188° C. is about half of that between 0° and −20° C. The mean coefficient of expansion of water in passing from 4° to −10° is −0·000362, and from 4° to 40° C. it is 0·0002155. Hence the mean coefficient of expansion of ice between 0° and −188° C. is about one-fourth of that of water between 0° and −10° C., and half of that between 4° and 100° C.

If we had the densities of ice at still lower temperatures, the values of the coefficient of expansion thence determined would, there is every reason to believe, be less than what we have found. We shall therefore not be overstraining the argument if we use the value just found to determine an upper limit to the density of ice at the absolute zero. The result is 0·9368, corresponding to a specific volume 1·0675. Now the lowest density of water, namely, at the boiling point, is 0·9586 (corresponding to specific volume 1·0432), so that ice can never be cooled low enough to reduce its volume to that of the liquid taken at any temperature under one atmosphere pressure. In other words, ice molecules can never be so closely packed by thermal contraction as the water molecules are in the liquid condition, or the volume of ice at the absolute zero is not the minimum volume of the water molecules. It has been observed by Prof. Poynting ("Change of State, Solid, Liquid," *Phil. Mag.* 1881) that if we supposed water could be cooled without freezing, then taking Brunner's coefficient for ice, and Hallstrom's formula for the volume of water at temperatures below 4° C., it follows that ice and water would have the same specific volume at some temperature between −120° and −130°; applying the ordinary thermodynamic relation, then no change of state between ice and water could be brought about below this temperature. On the other hand, Clausius ("Mechanical Theory of Heat," p. 172, 1879) has shown that the latent heat of fusion of ice must be lowered with the temperature of fusion some 0·603 of a unit per degree. If such a decrement is assumed to be constant, then about −130° the latent heat of fluidity would vanish.[1] Baynes discusses the same subject ("Lessons on Thermodynamics," p. 169, 1878) and arrives at the conclusion that at a temperature of −122°·8 C. and under a pressure of 16,632 atmospheres there is no distinction between the solid and liquid forms of water. At temperatures below this limit, no amount of pressure would transform ice into water. We are thus relieved from a difficulty that would follow but for this demonstration of Clausius, namely, that the application of enormous pressures to ice, even at temperatures below that of liquid hydrogen, might cause the transformation of ice into water.

Carbonic Acid.—Two experiments were made with this substance, the masses in each case being about 20 grammes. These were compressed cylinders; the former was compressed dry, while the latter was slightly moistened with ether. The density at −188°·8 C. was found to be 1·6308 and 1·6226.

The density of solid carbonic acid at its boiling point was formerly given as 1·5 (see *Proc. Roy. Inst.*, 1878, "The Liquefaction of Gases"), but the mean of my results at the time came to 1·53. Recently the same value has been found by Behn. Taking this value and 1·6267, the mean of the above results at −188°·8 C, and using the formula

$$d_T = d_{T'}\{1 + \alpha(T' - T)\}$$

we get $\alpha = 0·0005704$.

This is a very large coefficient of expansion, being greater than that of any substance recorded in the accompanying table, and comparable with that of sulphur between 80° and 100°, which, according to Kopp, is 0·00062. The coefficient of liquid carbonic acid at its melting point taken from the recent observations of Behn (*Chem. Soc. Journ.*, 1901) is 0·002989, so that the rate of expansion of the liquid at its smallest value is very nearly five times that of the solid.

Solid Mercury.—One experiment was made with solid mercury, and the result is given below.

Mallet determined with great accuracy the density of solid mercury at −38°·85, his result being 14·193; coupling this with the density found for the liquid-air temperature, we find that the value of the coefficient of expansion between the melting point and −189° C. is 0·0000887. For fluid mercury above 0° C. the mean value is about 0·000182, so that in the solid state this coefficient is about half of that in the fluid state.

The coefficients of expansion (α) obtained were as follows:—

	α 0·00
Sulphate of aluminium (18)[2]	0811
Biborate of soda (10)	1000
Chloride of calcium (6)	1191
Chloride of magnesium (6)	1072
Potash alum (24)	0813
Chrome alum (24), large crystal	0365
,, ,,	0478
Carbonate of soda (10)	1563
Phosphate of soda (12)	0787
Hyposulphate of soda (5)	0969
Ferrocyanide of potassium (3)	1195
Ferricyanide of potassium	2244
Nitro-prusside of sodium (4)	1138
Chloride of ammonium, sample i	1820
,, ,, sample ii	1893
Oxalic acid (2)	2643
Oxalate of methyl	3482
Paraffin	3567

[1] In my paper "On the Lowering of the Freezing-point of Water by Pressure" (*Roy. Soc. Proc.*, 1880), it was proved that up to 700 atmospheres the rate of fall was constant and equal to the theoretical value within the range of pressure if the difference between the specific volumes of ice and water remains constant; thence the latent heat of fusion must diminish just as Clausius had predicted.

[2] The figures in brackets refer to the number of molecules of water of crystallisation.

	$\frac{\alpha}{1000}$
Naphthalin	3200
Chloral hydrate	1482
Urea	1579
Iodoform	2930
Iodine	2510
Sulphur	1152
Mercury	0887
Sodium	1865
Graphite (Cumberland)	0733

Sodium, extending down to low temperatures, has a coefficient about the same as that of mercury at the ordinary temperature. The coefficient for sulphur is about half of that between 0° and 100°, being 0·0002237, and that of iodine is not far removed from the value 0·000285 given for the solid at ordinary temperatures. The rate of expansion of liquid iodine is about three times this value. Paraffin ought to have a value of 0·0004633 from Fizeau, but Rodwell's coefficient between 0° and 38° is 0·00035. The value found for naphthalin is about half that of the liquid near its melting point, viz. 0·000785. If the liquid coefficient be taken at a corresponding temperature to that of the liquid carbonic acid when comparing it with the solid, then its value is 0·001213, or the coefficient would be now in the ratio of 4 to 1. The graphite calculated from Fizeau should be 0·0000929, which is greater than my value; but the samples were different. My two specimens of chloride of ammonium gave nearly the same value, and the result is in agreement with that found by Playfair and Joule, viz. 0·000191. If a Fizeau coefficient for this salt is calculated, the value is 0·0000761, which in this case is far too small. The coefficient found for oxalic acid is again only a little smaller than that given by Playfair and Joule, viz. 0·0002748. As regards the hydrated salts, phosphate of soda, hyposulphate of soda and chloride of calcium, having the respective values 0·0001384, 0·0001516 and 0·0006887, as found by Kopp, the low temperature coefficients are much smaller in each case. With the exception of carbonate of soda and chrome alum, all the other hydrated salts have a coefficient of expansion not differing greatly from that of ice at low temperatures. Generally, the densities of the compressed blocks of different bodies agreed well with the results of other observers, but my potash alum had only a density of 1·614, whereas Playfair and Joule give 1·731. It will be noted that iodoform is a highly expansive body like iodine, and that oxalate of methyl has nearly as great a coefficient as paraffin, which is one of the most expansive solids. The correcting factor was used for paraffin, naphthalin, chloral hydrate, iodoform and sodium.

It will be possible by cooling the moulds with liquid air during the process of hydraulic compression to produce cylindrical blocks of solid bodies of lower melting-points than any given in this investigation, such as alcohol, ether, nitrous oxide, ammonia, chlorine, &c., and to ascertain their coefficients of expansion in the solid state between the individual melting points and the boiling point of liquid air.

This method, which works well with liquid oxygen or air, fails when applied to liquid hydrogen, as the density of the liquid is too small (apart from other difficulties) to give accurate values of the weights of fluid displaced. For temperatures about 20° absolute, recourse must be had to measurements of the coefficient of linear expansion, and such observations could only be applied with ease to metallic bodies and alloys.

THE RISE OF THE EXPERIMENTAL SCIENCES IN OXFORD.[1]

IN the Middle Ages, the scholars swept in flocks, like migrating birds, from school to school. What we now call a University was then no particular spot on the earth; but, like the ark in the wilderness, moved whithersoever a great teacher, such as Fulbert, the Anselms, Abélard, Peter Lombard, unfurled his standard. This mobility was, indeed, a guarantee of the freedom and the power of learning.

The "Civitas Philosophorum," as Saint Thomas called Paris, was engaged in 1209 in burning all the works imputed to Aristotle. This attack "on the Lehrfreiheit" of Paris, when the culture of the first renascence was streaming into Europe from the Arabian sources, drove its scholars abroad, and flights of them came to the comparatively unknown schools of Oxford and Cambridge. Oxford, already a centre of public affairs, sprang more suddenly than Cambridge into fame—on the scholastic side under the influence of the Friars Minors.

The Grey Friars, then breathing the humane spirit of their founder, stood for the people and for freedom, while the Friars Preachers were on the side of authority. Robert Grosseteste, who made Oxford as Abélard made Paris and Fulbert made Chartres, and his pupils, Adam Marsh and Roger Bacon, became Greek scholars of no inconsiderable attainment at a time when the potable gold of Greek tradition had virtually died out in the west, and with it the inspiration of natural knowledge. Adam Marsh, himself a Minor, was a statesman, a close friend of Simon of Montfort, and a champion of freedom of learning. Balliol was founded under Franciscan influences, and under this first temper in the next century, then in the teeth of the Minorites, Oxford was keenly Lollard; and with the suppression of Lollardism all intellectual life deserted her courts. Nevertheless, Oxford during the Middle Ages was a child of Paris rather than of Italy, whence Cambridge drew much of her nourishment, and was the picturesque stronghold of hierarchical traditions. Albert of Cologne, himself a Franciscan, vindicated against Paris the science of the Arab schools, and dignified the study of natural knowledge and experiment.

Pioneers of science may be divided into two kinds, into a group who, like Galileo, Boyle and Harvey, were themselves discoverers, and a second group, like Roger Bacon, Telesio, Patrizzi, Campanella, Francis Bacon, Ramus and Marsiglio, who did service rather as protestants and reformers of method. Whether Roger Bacon were more of a chemist than Albert of Cologne, or whether either got beyond the chemistry of Geber, whether Bacon advanced in optics, his special study, beyond Al Hazen, it is less important to ascertain than to declare that Bacon's title to fame is that he revived true methods of investigation. Many ancients had made experiments; Aristotle made many, Pliny made many; Bacon first declared that it was not experiment, but the experimental method, which was to regenerate science. We must not suppose that Roger Bacon was alone, as one crying in the desert; with the Arab illumination, natural science was in the air. Many voices, such as that of Peter of Méricourt, to whom Bacon regarded himself as indebted, preached experiment and contemned authority in natural research. The works of Nemorarius of Borgentreich, who first advanced from the statics of Greek and Arab to dynamics, were known to Bacon. The parabolic mirror and its focus were known to Al Hazen. Grosseteste had larger views than either Hales or Albert, and was no inconsiderable geometer. He wrote a treatise, "de Iride et de Cometis," and was a keen inquirer into the new sources of knowledge, including the "Res Physica," or medicine. Thomas Bungay, the eighth Provincial of the Friars Minors, was engaged with Bacon at Oxford in natural investigation, and, like other such inquirers, was regarded as a wizard. In Italy natural science continued, even in some abundance of life; but in Paris on the Isis, as in Paris on the Seine, its rudiments were soon buried under the Aristotelian and Galenical cenotaph by that busy gravedigger, Duns the Northumbrian, and were not dug up again until the day of Abbot Maurolycus and Vesalius nearly three centuries later. Thus one of the most piercing intellects and one of the most progressive societies our land has produced founded no school.

The great experimenters of the thirteenth as well as of the sixteenth and seventeenth centuries could hardly obtain skilled craftsmen for the construction of apparatus. Many observers, however, were themselves ingenious constructors—such as Archimedes, Hero, Leonardo, Brahé, Gilbert, Galileo, Huyghens, Hooke, Papin and, in our own time, Faraday and Ludwig. Roger Bacon, in his expenditure of money and labour upon machines, preceded Boyle and Hooke. We are not to suppose that Roger's machines were clumsy and rudimentary. The Alexandrian and Byzantine Greeks, and after them the Arabs, had constructed apparatus of surprising elaboration and ingenuity, and Bacon's machines would be well abreast of their time. In the sixteenth century, again, the reappearance of Greek preceded a new birth of natural science; although, unless at Wittemberg or Basel, freedom of speech was more closely stifled in Europe than in the time of Abélard, for Calvin himself bowed before Aristotle. William Solling, Linacre, Grocyn and Colet were therefore forerunners of the brilliant scientific revival of which, in the seventeenth century, the establishment

[1] Abstract of the Boyle Lecture delivered at Oxford on May 13 by Prof. T. Clifford Allbutt, F.R.S.

of the great scientific societies, the Lincei, the Paris Academy and the Royal Society, were the organs and the witnesses. We find in the life of Bruno a vivid narrative of the Oxford of the sixteenth century. Bruno visited Oxford in June, 1583, with the French Ambassador Castelnau, the translator of Ramus. Of the disputations in the schools, of their pompous frivolity, he gives a very amusing description. The earth, said Aristotle, Paris and Oxford, is motionless; the universe is finite and moves. Bruno, in the name of Philolaus and Copernicus, protested that the earth revolves and that the universe is infinite; and the dispute grew venomous. Bruno asked and was granted permission to teach in Oxford; but as *dormitantium animorum excubitor* he seems to have been even less successful in combating the physics of Aristotle than was Ramus in respect of his dialectic and Luther of his ethics.

Orthodoxy is the defensive weapon of society rather than of religion; when the needs of the two came into conflict it was religion which went to the wall. Happily "certain extravagant chemists," of whom more anon—and the Ramists, Paracelsians and Italian philosophers, were shrewdly assisted by new factors in the worlds of polite society and letters. As Petrarch and Boccaccio disarmed the academic coxcombs of Padua, now again in France the sceptical bonhomie of Montaigne, the revolutionary philosophy of Charron, the merciless raillery of the Mariage Forcé and the polished satire of Boileau did more to penetrate the armour of the Church than the hardier rebels to bruise it. By them the shabby Aristolelian effigy, battered by the weapons of Roger Bacon, of Galileo, of Harvey, of Telesio and Descartes, and bedaubed with the missiles of Patrizzi, of Ramus and of Verulam, was finally broken up and demolished. In the middle of the seventeenth century at Wadham, Warden Wilkins gathered about him a constellation of scientific men such as has perhaps never gathered together in any other time or place. Robert Boyle, Christopher Wren, John Locke, Robert Hooke, and, but little latter, John Mayow, all of them men of genius, were at the head of a society which was the foundation of the Royal Society, and among its lesser lights contained names no less than those of Seth Ward, John Wallis, Thomas Willis, Roger Lower and William Petty. The lecture concluded with a study of Boyle, not only as a scientific discoverer, but also as a philosopher and a reformer of method of far greater insight than Dr. Whewell admits, and, moreover, a man of charming temperament and an accomplished man of letters.

ANTHROPOLOGICAL RESEARCHES IN INDIA.[1]

LIEUT.-COLONEL DR. WADDELL has been constrained to make a careful study of the savage tribes that live in the mountainous valleys of the upper waters of the Brahmaputra, as he realised that the unique mass of ethnological material which is stored in these mountain recesses is being allowed to disappear unrecorded. It is said to be no uncommon sight to see a Naga, who only two or three years ago was a naked head-hunting savage of the most pronounced type, now clad in a tweed coat and carrying a Manchester umbrella, taking his ticket at a railway station. Dr. Waddell states that one of the oldest European residents of Assam, Mr. S. E. Peal, urged at every opportunity in the public Press and in communications to the Asiatic Societies, the Royal Geographical Society and the Anthropological Institute of London, in the strongest terms possible, the necessity for action without further delay. In despair at the apathy displayed in the matter, he willed away at his death, a few months ago, to a museum in New Zealand all his collections of miscellaneous notes and specimens of the vanishing ornaments and primitive costumes of these wild tribes. Colonel Woodthorpe has emphasised the loss to ethnology if the many interesting tribes are not carefully studied soon. Mr. Wharry, adviser on Chinese affairs to the Government at Burma, says:—"The chance of studying these peoples to full advantage is fast slipping away."

The observations published by Dr. Waddell relate to about 600 individuals belonging to more than thirty tribes or groups. After briefly describing the influence of topography on the ethnology of the district and the racial elements, he gives a short account of a large number of tribes in alphabetical order. This section contains a great deal of very interesting matter which is of value alike to the ethnologist and to the student of comparative customs. Then follows the detailed anthropometric data and seventeen plates of portraits and groups. As the tables of indices and the "comparison of the results and the bearing of these on the question of the affinities of the tribes" are not given in this part, we assume they will follow in the next number of the journal, when it is to be hoped the equally bulky data for the tribes of Tibet and Burma, which the author has amassed, will be published for the benefit of his colleagues at home.

The laborious work accomplished single-handed and mainly at his own expense by Colonel Waddell deserves our warmest thanks, and we hope he will feel that anthropologists thoroughly appreciate his self-denying labours. It is quite beyond the power of the few students at home to help in supporting, save by encouragement, such workers as Colonel Waddell. To our shame be it spoken, there is no organisation by which the wealth of those who have abundance can be directed towards the pressing needs of field-work among primitive peoples, such as is so pathetically advocated by the author of this paper, and our Government also is apathetic to the study of native races; one can only hope that this negligence is due to ignorance.

Since Colonel Waddell wrote his paper, the Government of India has undertaken to conduct an Ethnographic Survey of India in connection with the census of 1901. This action was due to the initiative of the British Association at the Dover meeting in 1899; particulars of the proposed scheme of work will be found in *Man*, September 1901, p. 137. As Mr. Risley, the author of "The Tribes and Castes of Bengal," has been appointed Director of Ethnography for India, we may feel sure that the Survey will be wisely planned, and we sincerely hope that sufficiently skilled workers are employed and that the usefulness of the Survey will not be impeded through lack of funds. While we are thankful for this official recognition of the claims of anthropology, it is still necessary to repeat, what has so often been urged in the pages of NATURE, that there is an enormous mass of ethnological material in our Empire beyond the seas which is yearly decreasing at an alarming rate, or is rapidly becoming so modified as to lose its original value. The loss of this vanishing anthropological information is supinely permitted by our Government. What a contrast there is between the British Government and that of the United States is known only too well by those acquainted with the annual reports of the Bureau of Ethnology.

Mr. T. H. Holland, of the Geological Survey of India, has published a very valuable study on two well-contrasted human types found in a small district of southern India. The presentation of the data, their discussion, the comparative tables, diagrams and plates, render this a model paper.

In the little province of Coorg, which embraces a semi-isolated portion of the western Ghats, there is an interesting instance of the way in which a mountainous and jungle-covered country has been turned to totally different purposes by two distinct races. The agricultural Yeruva early retreated into the little mountain province before the aggressive invaders. At a later period the splendid Kodagas (Coorgs) found in the jungles of Coorg the means of satisfying their hunting propensities, whilst the narrow passes suited their highly developed instincts for predatory raids into the country of their wealthier but less warlike neighbours. The sporting and fighting proclivities of the Coorgs reveal themselves even in their festive and religious ceremonies. From his very birth, when a miniature bow and arrow made from the castor oil plant is placed in the hands of the baby boy, the Coorg male is, or was, regarded as a huntsman and a warrior whose pride was in his size and strength; hence this is the finest race in the south of India.

A comparison of the physical characters of these two tribes proves that the Coorg is on an average 3·9 inches taller than the Yeruva, and with a relatively shorter span he has a larger and broader head, a more perfect approach to orthognathism, his nose is longer and narrower. There is a marked contrast between the fair (light brown), straight-haired Coorg and the very dark-skinned Yeruva, whose hair is distinctly wavy. The features of the latter are generally of the stamp which we should characterise as distinctly low, the broad nose being accompanied by thick, slightly everted lips.

[1] "The Tribes of the Brahmaputra Valley: a Contribution on their Physical Types and Affinities." By L. A. Waddell, M.B., LL.D., Lieut.-Colonel, Indian Medical Service. (*Journal* of the Asiatic Society of Bengal, vol. lxix., part iii. 1900 1901) pp. 1-127. pls. ii-xviii.)

"The Coorgs and Yeruvas, an Ethnological Contrast." By T. H. Holland, A.R.C.S., F.G.S., Geological Survey of India. (*Ibid*, vol. lxx. part iii. 1901, pp. 59-98, pls. i-v.).

The Coorgs and the Yeruvas belong to two distinct ethnic types. The latter tribe falls into a group with the Kurumbas, Irulas, Paniyans and Kadirs, who have been so ably studied by Mr. Thurston and are the South Indian cousins of the Kols and Gonds living on the central highlands. In all their physical characters the Coorgs differ from the Yeruvas, and, indeed, they possess more of the superior characteristics which are supposed to indicate an Aryan origin than do many of the South Indian tribes who claim a higher caste position, and fewer signs of aboriginal blood than even the Brahmans of the Madras Presidency. Their almost brachycephalic index of 79·9, however, leaves the question of their ethnic relationship an unsolved problem.

A. C. H.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD. The Rolleston memorial prize for original research in morphology has been awarded to Mr. Francis J. Cole, Jesus College.

CAMBRIDGE.—The Balfour managers have made grants for zoological research in Africa to Mr. C. Crossland and Mr. J. S. Budgett.

An exhibition of astronomical photographs from the Yerkes and Lick Observatories will be given at the Cavendish Laboratory on May 29 by Sir Robert Ball.

Applications for tables at the Naples and at the Plymouth zoological stations should be addressed to Prof. A. Newton by June 5 next.

The complete degree of M.A. *honoris causa* is to be conferred on Mr. T. H. Middleton, the new professor of agriculture.

Mr. W. B. Hardy and Mr. F. G. Hopkins have been appointed examiners for the Gedge prize in physiology.

The Thurston prize for original research in physiology, pathology or practical medicine, open to members of Gonville and Caius College of not more than fifteen years' standing from matriculation, will be awarded this year. The prize is triennial and amounts to about 54*l.* Applications are to be addressed to the master on or before September 30.

A CONVERSAZIONE will be held at University College, London, on Thursday, June 19. A large number of friends and old students will be present, and exhibits will be arranged in connection with the various departments, to illustrate the work being carried on at the College.

THERE is every likelihood that another University will soon be added to the large number of such institutions at present existing in the German Empire. Frankfort a. M. is the city which is thus to be enriched. It already possesses the Senckenberg's Institute for natural sciences and medicine, and also an academy for the study of social and commercial science. To the former—at which, it may be mentioned, important scientific work is carried on—there has recently been added a laboratory specially constructed for the investigation of cancer. This department is richly endowed, partly, it is said, by the Emperor William, and is placed in the care of an eminent bacteriologist. The academy is very largely attended by foreign as well as German students, America in particular being well represented. And now it is announced that the trustees of the Karl Juegel's bequest have decided to devote the interest on the capital sum of 2,000,000 marks (100,000*l.*) to the erection in Frankfort a. M. of an academy for the study of history, law, philosophy and allied subjects. When this third institution is established, Frankfort will possess practically all the faculties, with the exception of theology, which go to form an University; and therefore the authorities have decided to draw up a Bill which, if passed by Parliament, will unite the three institutes of learning into one University. There is strong reason to suppose that no particular difficulty will be encountered in carrying out this plan, for Frankfort is in many ways eminently suitable for the position of being an University city.

NOW that the second reading of the Education Bill has been passed, efforts should be made in Committee to remove the permissive clause, especially in so far as it affects higher education. At present, as Mr. Henry Hobhouse points out in a letter to the *Times*, there is little more than a framework for legislation. "No statutory duty is laid on the local authority to aid education 'other than elementary,' and no permanent fund is appropriated for this object. The 'whisky money' is not safeguarded, despite the obvious danger that the ratepayers in certain localities will press for compensation out of this fund for the additional burdens necessitated for the purposes of elementary education. Nor are the objects of higher education in any way defined. The intention of the Government apparently is (though it is not expressed in the Bill) to impose on the new authority the provision of evening continuation schools, pupil teachers' centres, and even training colleges. The restrictions of the Technical Instruction Acts on aiding private profit schools and on teaching trades are swept away. In a word, under part ii., as it now stands, it would seem that a local authority may do anything and need do nothing. Surely Parliament ought to give more guidance than this to the new authorities, or there will be great danger that in certain localities most important developments of educational work will be wholly or partially neglected." As the Bill at present stands, there is a danger that the last case of higher education will be worse than the first.

AT the presentation day of the University of London, on May 14, Lord Rosebery was welcomed as the new Chancellor. Principal Rücker read his report upon the work of the University during the past year, and referred to the following points among others. The organisation of the University has been completed by the addition of a new department for University extension and the inspection of schools. Regulations have been passed for the admission of post-graduate students from other Universities to study for the doctorate in London, and it is satisfactory to be able to record that a considerable number of such students are, or are about to be, placed upon the books of the University. Two chairs of chemistry are to be established at University College, one for general chemistry, which will be filled by Prof. Ramsay, the other for organic chemistry. In no subject has the difference between the completeness of English and foreign educational equipment been more marked than in chemistry. Only two or three educational institutions in this country have more than one professor of chemistry, while in Germany even a University of the second-class usually has several professors in that department. It is hoped that the chairs now founded in University College will be the beginning of a great chemical department worthy of London. A very large scheme, which will have an important bearing on the future organisation of the University, has been set on foot in consequence of the munificent offer of the Drapers' Company to give 30,000*l.* in aid of the incorporation of University College in the University. The authorities, both of the University and of the College, have agreed in principle to the main outlines of a plan for incorporation, provided that an initial sum of 110,000*l.* can be raised. There is every reason to hope that this condition will before long be fulfilled. While the University has been engaged in entering into closer relations with the various schools, and in negotiations for the complete absorption of one of them, it has also been undertaking teaching on its own account. All the leading physiologists in London have banded themselves together to give courses of lectures on that subject for advanced and post-graduate students, and Mr. Walter Palmer has generously given a sum of 2000*l.* to enable the experiment to be tried as to whether such lectures would attract an adequate number of students. The University has contributed another 400*l.*, and has also placed a suite of rooms in the University buildings at the disposal of the teachers as laboratories and lecture rooms. To obtain an idea of the research work being done in London, recognised teachers of the University were asked to supply a short statement as to the publications of themselves, their assistants and students during the past twelve months. Nearly six hundred memoirs, papers and minor communications to scientific and literary journals have been reported. As might have been expected from the large number of its members, the medical faculty takes the lead in the number of its publications, somewhat less than half the above total being communications to professional medical societies and journals. Teachers of the University, their assistants and students have made about 220 additions to general scientific literature. They have been the authors, or joint authors, of eleven papers in the *Transactions* of the Royal Society, or of about eighty papers which have appeared in the *Proceedings* of the Royal Society, and in the journals of the Chemical, Linnean, Physiological and other kindred societies. University College heads the list

with a total of about 100 memoirs and papers, while the Polytechnics have contributed about a score. In concluding his report, the Principal remarked: "It is time that London should realise that it is not the want of men, or a dearth of intellectual effort, which has hindered the University of London from taking its place as a great centre of teaching and research. Our needs are organisation, which shall make the results of the work of the teachers, their assistants and students more fruitful and better known as results of which London may be proud, and funds to supply them with the materials for their work."

SCIENTIFIC SERIALS.

American Journal of Science, May.—Notes on living Cycads, by G. R. Wieland. A study of *Zamia floridana*. Particular attention is drawn to the presence on one of the cones of a pinnule of normal form and structure which had grown out from beneath the outer hexagonal tip of one of the upper abortive sporophylls. As in a similar example described by Sir W. T. Thiselton-Dyer, this structure is regarded as a reversion, exhibiting evolutionary stages which may be found in fossilised forms. To speak of these growths as "monstrous cones" is regarded as almost misleading.—On crystals of Croconite from Tasmania, by R. G. Van Name.—Notes on unusual minerals from the Pacific States, by R. W. Turner. Among the phosphates found were pyromorphite, apatite and monazite, the latter occurring in abundance in the Idaho basin.—On the use of the stereographic projection for geographical maps and sailing charts, by S. L. Penfield. A continuation of previous papers on the same subject.—Note on the application of the phase rule to the fusing points of copper, silver and gold, by T. W. Richards. It has been found by Holborn and Day that gold gives a very constant melting point, copper two constant points at 1065° and 1084° C., whilst silver gives no fixed point. It is shown that all these results could have been deduced by the application of the phase rule.—The initiative action of iodine and other oxidisers in the hydrolysis of starch and dextrins, by F. E. Hale.—Note on the possibility of a colloidal state of gases, by C. Barus.—Some glacial remains near Woodstock, Connecticut, by J. W. Eggleston.

American Journal of Mathematics, vol. xxiv. No. 2, April.—L. E. Dickson, on the canonical form of a linear homogeneous transformation in an arbitrary field of rationality. In a previous paper (*A. J.* xxii. p. 121) the author obtained a reduction to a canonical form for transformation in a Galois field; it is here proved that the same process applies when the field is arbitrary.—H. B. Newson, a new theory of collineations and their Lie groups. A geometrical theory of collineation in the plane, independent of Lie's analytical method of transformation-groups.—L. P. Eisenhart, infinitesimal deformation of surfaces. A discussion of the transformation $x' = x + \epsilon x_1$, $y' = y + \epsilon y_1$, $z' = z + \epsilon z_1$, with $dxdx_1 + dydy_1 + dzdz_1 = 0$, and ϵ a small constant, of which the square is neglected.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 6.—"On the Spark Discharge from Metallic Poles in Water." By Sir Norman Lockyer, K.C.B., F.R.S.

In this paper various modifications produced in the spectra of metals by alterations of the conditions under which the substances are volatilised are discussed and new observations made at the Solar Physics Observatory are described. The investigation was undertaken partly in consequence of a suggestion put forward by Dr. Wilsing, of Potsdam, to the effect that certain conditions, viz. the production of spark spectra in liquids, gave rise to the formation of structural peculiarities in the constituent lines which are characteristic of the spectra of new stars.

One of the chief characteristics of the spectra of Novæ is the occurrence of a series of double lines, each consisting of a bright and a dark component, the latter being always situated on the violet or more refrangible side of the bright line and in contact with it. The usual interpretation of this appearance has been to consider the composite spectrum produced by two bodies in relative motion, but the necessary velocity is greatly in excess of other known cosmical motions. Recent experiments dealing with the spectra of elements under pressure having shown that by this means the wave-lengths of the lines are altered, Dr. Wilsing suggested that if the pressure were sufficiently great, displacements might be obtained of equal magnitude to those observed in the case of new stars. As the direct application of high pressures is attended with difficulties, he utilised the fact that exceedingly high tensions are produced when electric sparks are discharged in liquids.

Using an induction coil, with jar and air break in the secondary circuit, a brilliant discharge is produced in water, giving a very intense continuous spectrum crossed by faint metallic lines. In this way Dr. Wilsing obtained the spectra of iron, nickel, platinum, copper, tin, zinc, cadmium, lead and silver, and from the examination of the photographs he arrived at the conclusion that displacements of lines and double lines occurred which were in every way similar to those in the spectra of Nova Aurigæ, and that therefore, in all probability, pressure is the cause of the duplication and broadening of the lines in the spectra of new stars.

On examining the first few spectra obtained under these special conditions, the appearances presented were so suggestive of many of the well-known effects of reversal that a further inquiry was advisable. It has long been known that in ordinary arc spectra many instances occur in which the absorption line is asymmetrical with respect to the emission line; and reference is made in the paper to communications by the author to the Royal Society more than a quarter of a century ago describing these peculiarities in certain silver and rubidium lines.

The experiments at the Solar Physics Observatory were made first with the large Spottiswoode coil, capable of giving a 42-inch spark in air, this being intensified by the insertion of a large glass-plate-condenser in the secondary circuit, so that the sparks obtained were about 3 mm. long in air and 0·5 mm. in water.

Later a 10-inch coil was used with a smaller condenser in circuit, and about the same sparking conditions. The photographs of the spectrum were taken on a large scale by means of a 6-inch Rowland concave grating of 21·5 feet radius, with 14,438 lines to the inch. The first-order spectrum was employed, arranged to photograph the region from λ 3800 to λ 4800, occupying a length of 18 inches on the plate. Distilled water was used in all cases.

Of the metals examined (iron, silver, lead, copper, zinc and magnesium) only iron, magnesium and zinc showed reversals, and those of zinc were extremely weak. In all cases the lines of the spectrum of the spark in water are much broader than the corresponding lines in the spectrum of the air-spark. From an examination of several plates of different intensity, however, it appeared that the broadening was, for the most part, of similar nature to that observed in the arc spectrum in air when an excess of material is introduced between the poles.

When the cases of non-symmetrical absorption were considered, it was noted that very different appearances were presented according to the exposure of the spectrum. For example, in the best exposed plate of iron, the line at λ 4260·64 is well reversed in the water-spark, with the part of the emission line towards the red several times stronger than the portion on the violet side of the absorption. An even diminution of the whole composite line, as shown by photographs of less exposure, results in the persistence of the less refrangible portion only of the emission line, which alone would suggest the presence of a line greatly displaced towards the red with regard to the original spark line in air. Several of the iron lines show the intermediate stage, where the violet component is on the verge of visibility, and in these cases the appearance is suggestive of a bright line with a dark companion on its more refrangible border. It is important to note, however, that in these cases the absorption line is usually normal with the position of the original line, the bright component being displaced towards the red.

In the water-spark spectrum of copper it is only with difficulty that any existing line spectrum can be distinguished from the intense continuous emission, and the few lines so recorded present the appearance of broad bands, displaced towards the red. The probability of their being produced in the manner suggested, however, is rendered feasible by the fact that, although no actual absorption is visible, their more refrangible edges are fairly sharply defined, while the other edges are quite diffuse.

A general classification of the phenomena which are thus presented under varying conditions is put forward, the grouping being as follows :—

(1) *Broadened bright line.* Examples of this stage are presented in the spectrum of copper and the under-exposed spectrum of iron.

(2) *Broadened bright line with central absorption line.* Well shown in the central line of the violet triplet of iron, λ 4063·76.

(3) *Broadened bright line with non-symmetrical absorption* (*maximum of emission towards red*). A good example of this is the iron line at λ 4260·64.

An additional feature of the water-spark spectrum is that many of the lines show inversion of intensity with respect to the air spark spectrum. This is well shown in the lines of iron at λλ 4422·74 and 4427·48.

From these considerations it appears that, if suitable exposures are given, lines may be photographed in the spectrum of iron, say, which show all the phenomena described by Dr. Wilsing, but so related to each other and the complete stage—that of reversal, symmetrical or unsymmetrical—that it is impossible to regard them as anything abnormal.

Again, when these appearances are contrasted with the structure peculiar to the spectra of Novæ, many divergences of vital importance are found.

In the water-spark the position of the absorption undergoes little if any change of position, while in the case of non-symmetrical reversals, a bright line may be observed greatly displaced towards the red. In the new stars, on the other hand, the absorption lines are greatly displaced, the accompanying bright lines occupying in comparison normal positions. Thus, in the case of Nova Aurigæ the emission lines had practically normal wave-lengths, but the displacements of the dark lines at H_ϵ were about 10·7 tenth-metres towards the violet, indicating a velocity of approach of about 500 miles per second. The recent new star in Perseus exhibited the same normal positions of the bright lines, and indications of even greater displacements of the dark lines, at one time amounting to 15 tenth-metres at H_ϵ, representing a velocity of approach of the body producing the dark-line spectrum of more than 700 miles per second. These values differ enormously from those produced by pressure.

It appears then that the known direct effect of pressure on the radiation or absorption lines is the same, in quality, in water as in air, that is, displacements are obtained in the *opposite* direction to those the dark lines are observed to occupy in the spectra of Novæ ; moreover, the amount of shift observed in the spectra of new stars differs, not only in this respect, but also in degree, thus :—

Spark in water.	New stars.
1. Absorption lines least shifted.	Absorption lines most shifted.
2. Radiation lines most shifted.	Radiation lines least shifted.
3. Absorption shift small.	Absorption shift enormous.

It would thus appear that the pairs of bright and dark lines shown in the spectra of new stars do not arise from the cause, presumably pressure, which produces the appearances presented in the spectrum of the spark discharge in water.

Royal Astronomical Society, May 9.—Dr. J. W. L. Glaisher, president, in the chair.—Mr. H. C. Plummer read a paper on the accuracy of photographic measures, in which he criticised M. Lœwy's recent memoir on the subject. Mr. Plummer doubted the possibility of expressing by a single formula the probable error of measures of stars on photographs, and considered the question of personality in estimating the centre of star photographic images. The paper gave rise to some discussion, in which Mr. Hinks, Prof. Turner and others took part.—Father Cortie read a paper by Father Sidgreaves on the spectrum of Nova Persei from September 6, 1901, to February 12, 1902, and showed photographs on the screen. During the period mentioned, the lines of the spectrum had remained very broad and preserved their relative intensities.—Father Cortie read a paper on visual and spectroscopic observations of the sun-spot group of May and June 1901. It appeared that the disturbed area of the corona of May 18, as shown on the eclipse photographs, corresponded with the region in which the spot group had its origin, and marked the time of the outburst, though the region had been disturbed quite a solar rotation before the birth of the spot. In this case of the only great sun-spot in an otherwise quiet year there appeared no correspondence between solar storms and terrestrial magnetic disturbance. The most widened lines in the red end of the spectrum of sun-spots are always faint lines, chiefly of vanadium and titanium. The author concluded that the level of sun-spots is that of the upper, more diffused gases, which give the flash spectrum in solar eclipses. In the discussion which followed, doubt was thrown upon the presence of vanadium in the flash spectrum.—Mr. Dyson described the Greenwich photographic observations of the satellite of Neptune, and also gave an account of a paper by Mr. Cowell on a method of reduction of extra-meridian observations. The method was a general one, suitable for observations at any azimuth, and the computation was facilitated by tables.

Linnean Society, May 1.—Prof. S. H. Vines, F.R.S., president, in the chair.—Mr. J. E. Harting exhibited photographs of a living specimen of the African shoe-bill (*Balaeniceps rex*), forwarded from Cairo by Sir William Garstin, K.C.M.G., and gave some account of the bird and of the different views which had been expressed by zoologists regarding its affinities and systematic position.—On the cerebellum of the lemurs, by Dr. Elliot Smith. In this paper, to be published as an addendum to that on the cerebrum read on March 6, the author introduces a revised terminology. Resolving the cerebellum into three main lobes—anticus, medius and posticus, he discards the term "fissura horizontalis magna," since the fissure so named is found to be inconstant and sometimes absent, and substitutes for "preclival" the term *prima*, regarding the fissure thus named, which divides the lobus anterius and medius, as the deepest and as constant for all mammalian forms. The detailed characters of the lemuroid cerebellum are described, and the cerebellum of Notoryctes is incidentally shown to be the simplest for all mammals.—On the brain of the elephant shrew (*Macroscelides elephantopus*, Shaw), by Dr. Elliot Smith. The brain of Macroscelides is shown to be marsupial in the existence of a dorsal fornix commissure of crescentic type, unique in the coexistence with this of a distinct and independent callosum, equal in extent to that of the higher Primates. Comparison is drawn with the cerebrum of those higher Metatheria in which the fusion of callosum and fornix commissure (psalterium) is the rule ; and the author concludes that the examination microscopically of well-preserved material, of which he is expectant, will reveal a connection between these two which may not necessarily contain nerve-fibres, and may thus realise a condition he has previously described for the Hapalidæ.—On the early condition of the shoulder-girdle of the polyprotodont marsupials Dasyurus and Perameles, by Dr. R. Broom. The author shows that in the mammary fœtus of the native cat of Tasmania and Victoria

(*Dasyurus viverrinus*), the cartilaginous coracoid reaches the sternum, as he has previously proved to be the case in the fœtal Trichosurus. At a later stage, an elongation of the spine and clavicle is all conspicuous, with accompanying withdrawal of the coracoid. In the mammary fœtus of the bandicoot (*Perameles obesula*) described, the coracoid is found to exhibit no connection with the sternum, and the scapula to be essentially similar to that of the adult, the clavicle reduced.

Geological Society, April 30.—Prof. Charles Lapworth, F.R.S., president, in the chair.—Mr. J. E. Marr exhibited some specimens from a metamorphosed metalliferous vein several inches wide, which he had discovered in the basic andesites near the Shap Granite, in a quarry close to the high road, north of the spot where it crosses Longfell Gill.—Mr. H. W. Monckton exhibited a flint implement which he had himself found on a heap of gravel, in a pit 278 feet above Ordnance-datum, at Englefield (Berkshire). The gravel is part of an elongated patch mapped "Plateau-Gravel." Mr. O. A. Shrubsole remarked that the implement was of Palæolithic type, and of an advanced form of that type, as it had a cutting-edge all round. It had not been greatly rolled, and was probably made not far from the spot where it was found. Its patination showed that it belonged to the gravel in which it was found.—The origin and associations of the jaspers of south-eastern Anglesey, by Mr. Edward Greenly. Red jasper and jaspery phyllite are widely distributed in the southern and south-eastern parts of Anglesey, in the districts of Newborough, Pentraeth and Beaumaris. They are associated with limestones, diabases, serpentines, and with grits and shales. They have been much modified by earth-movements, which have produced brecciated and schistose structures; but where original structures have survived, the true relations of the rocks can often be seen. The diabases have the same characters as the pillowy and variolitic rocks so often associated with radiolarian cherts and jaspers in many parts of the world, and at several different geological horizons; and the relationships of the jaspers and igneous rocks resemble those seen in the radiolarian cherts of southern Scotland. It is inferred that the jaspers are altered radiolarian cherts.—The mineralogical constitution of the finer material of the Bunter pebble-bed in the west of England, by Mr. H. H. Thomas. Specimens were collected at intervals, from Budleigh Salterton, in Devon, to Fitzhead, near Milverton, in Somerset, and other sands, for comparison, were taken from the red rocks above and below. The sands, on the whole, contain a very small percentage of minerals with a specific gravity of more than 2·8; while the proportion of material over, to that under, 2·58 is about 70 or 80 to 30 or 20 per cent. A list and description of twenty minerals found in the sands is given, with, in some instances, the chief characters by which they were identified. The gradual decrease in the percentage of heavy minerals from Budleigh Salterton to Uffculm indicates the carriage of sediment by a southerly current, and this view is strengthened by the decrease in staurolite and a gradual diminution in the size of the tourmaline-grains. The increase in proportion of heavy grains from Uffculm to Milverton, and the further decline northward, together with the incoming of an assemblage of minerals markedly different from the normal southerly type, indicates an additional source of supply, perhaps a westerly current. The mass of material seems to have been furnished by a highly metamorphosed area, differing widely in its character from any now exposed in the south-west of England. The most probable source of much of the material is the Armorican massif of Triassic times.—Revision of the Phyllocarida from the Chemung and Waverly groups of Pennsylvania, by Prof. C. E. Beecher. The specimens described in the paper, as well as those on which the original descriptions were based, were all obtained in the vicinity of Warren, Philadelphia. The chief horizon is in the shale-beds of the Upper Chemung group, about 50 feet above mean water-level in the Allegheny River. The deposits are called by the writer the "Phyllocarid-Beds" Additions and emendations to the original diagnoses of several genera and species are given.

MANCHESTER.

Literary and Philosophical Society, May 13.—Mr. Charles Bailey, president, in the chair.—A paper on the luminous organs in *Pterygioteuthis margaritifera*, a Mediterranean cephalopod, by Mr. W. E. Hoyle, was laid upon the table.—Prof. Boyd Dawkins, F.R.S., brought before the Society the collection of specimens discovered in 1901 in Crete by Mr. Hogarth in the course of the exploration of the Mycenæan remains of that island. The skulls exhibited belong to the oval-headed, well-developed type termed Mediterranean by Sergi and closely allied to the Iberic type of Spain and of Britain. They bear unmistakable marks of civilisation in the thinness of their walls and the extent to which the sutures are drawn out by the growth of the brain, as well as by the badness of their grinders and the small size of their canines. They probably represent a small, dark race, and were in the Bronze stage of civilisation. Among the remains from the Dictæan cave are the skulls of a goat and a hog, portions of those of the fallow-deer, and the forehead with two horn-cores of a domestic ox, for which Prof. Dawkins proposes the provisional name of *Bos buticus*, as it cannot be identified with any species on record.

PARIS.

Academy of Sciences, May 12.—M. Bouquet de la Grye in the chair.—Notice on the works of M. Lazare Fuchs, by M. Camille Jordan.—A study of lithium silicide, by M. Henri Moissan. The discovery of a silicon hydride of the constitution Si_2H_6 suggested the possibility of the existence of a series of corresponding metallic silicides, and in the present paper the preparation and properties of the lithium silicide, Si_2Li_6, are described. A mixture of silicon with lithium in slight excess is heated in a vacuum at a low red heat for two or three hours and the excess of lithium distilled off between 400° and 500° C. The silicide formed, the analysis of which gave figures corresponding to the formula Si_2Li_6, forms deep blue crystals. With a small quantity of water, this silicide reacts very violently, a spontaneously inflammable mixture of hydrogen and hydrogen silicide being given off. The slow decomposition with water furnishes only pure hydrogen. It was noted that although a solution of hydrochloric acid gas in dry ether was without action on the compound, the addition of a small quantity of water caused a rapid decomposition.—On the earthquake of May 6, 1902, by M. Michel Lévy. Two records from seismographs show earthquakes on May 6, one at Grenoble at 3h. 4m. 40s., and the other at Floirac at 3h. 5m. 30s. On the supposition of a velocity of transmission of 3 kilometres per second, the epicentre should be in the Mediterranean, east of Murcie and south of Minorca.—On viscous compressible fluids, by M. P. Duhem.—The black coloration of the rocks forming the cataracts of the Nile, by MM. Lortet and Hugounenq. The specimens of granite and porphyry at the cataracts of Ouadi-Halfa and Assouan present a uniformly black and highly polished surface, facts difficult to explain from the composition of these rocks. The polish is attributed to the scouring action of the sand brought down by the water, the black colour to black oxide of manganese. The latter does not exist in the rock mass and must have been formed from the manganese silicates present.—On a project for the organisation of a service of scientific exploration in Indo-China. The committee appointed to consider this question recommend the appointment of a permanent commission under the control of the Academy, the subjects of geology (with mineralogy), botany, zoology and anthropology being represented.—Remarks by M. Janssen on presenting to the Academy photographs of the solar corona taken at the Isle of Reunion during the total eclipse of May 17, 1901, by M. Jean Binot. The photographs from this station were of especial importance on account of the want of success due to climatic conditions at the other places of observation. A whole-page reproduction of this photograph accompanies the note.—The influence of instrumental errors on the rectilineal coordinates of star photographs, by M. Ch. Trépied.—On some orthogonal systems and their application to the problem of the deformation of the paraboloid of revolution, by M. de Tannenberg.—On a class of transformations of partial differential equations of the second order, by M. J. Clairin.—On the prediction of the minimum yield of the sources of the Vanne, by M. Edmond Maillet. If the rainfall of a given winter season is plotted as an abscissa against the yield of the springs for the second quarter following, the results for a number of years fall on regular curves, which can thus be applied to the prediction of the supply for the coming season.—On the continuous spectrum of electric sparks, by M. B. Eginitis. The spectrum of ordinary electric sparks between metallic electrodes is usually accompanied by a continuous spectrum, the intensity of which is usually very small compared with the intensity of the line

spectrum. The intensity of this continuous spectrum varies in different places, and also varies with the self-induction of the circuit. It is very intense in the case of certain metals such as magnesium, iron, cobalt, nickel and manganese. For all the metals examined, the continuous spectrum can be completely eliminated by choosing particular values for the self-induction.—On a magnetic perturbation observed on May 8, by M. Th. Moureaux. A magnetic disturbance, affecting chiefly the horizontal component, was recorded at the Observatory of Val-Joyeux, near Saint-Cyr, at a time corresponding to the catastrophe of Martinique.—On a rain of ink on May 7, 1902, by M. Th. Moureaux.—On the conditions of formation and stability of the hydrides and nitrides of the alkaline earths, by M. Henri Gautier. In the case of the hydrides of barium and strontium, certain phenomena were observed which appeared to point to the possible existence of a higher hydride than BaH_2 or SrH_2, but on further examination these results were found to be due to the simple absorption of hydrogen by the hydrides without the formation of any definite compounds. Calcium hydride does not possess this property. The nitrides were found to be much more stable than the hydrides, commencing to form only at temperatures above 600° C., and remaining undecomposed at 1000° C., a temperature at which the hydrides are strongly dissociated.—On some derivatives of anthraquinone obtained by the action of sodium peroxide upon the aloins and their halogen derivatives, by M. E. Léger.—On a new dimethylglutaric acid, by M. E. E. Blaise.—The synthesis of menthone, by M. Georges Leser. The synthesis was effected by the action of potassium dissolved in absolute alcohol upon a mixture of isopropyl iodide and acetylmethylcyclohexanone. On the composition and age of the metamorphic rocks of Crete, by M. L. Cayeux. The metamorphic series of western Crete belongs to the Trias of the Mediterranean type, probably to the Upper Trias.—On certain chromatic reactions of the red corpuscles in the blood of diabetics, by M. J. Le Goff.

NEW SOUTH WALES.

Linnean Society, March 26.—Mr. J. H. Maiden, president, in the chair.—The president delivered the annual address.

Ordinary meeting.—Note on two species of Astralium from Port Jackson, by Mr. H. Leighton Kesteven. The author finds that *Astralium fimbriatum*, Lamarck, and *A. tentoriforme*, Jonas, have, in Port Jackson, been united under the latter name. He finds that in the nepionic stage the former is very depressed, almost discoidal, and perspectively umbilicate; whilst the latter is trochiform and not umbilicate, at the same stage. They present the anomaly of two species easily separable in the nepionic stage, becoming so alike in the adult condition that only by their opercula can some specimens be identified.—Studies on Australian Mollusca, part vi., by Mr. C. Hedley. Material from tropical Queensland furnishes two genera, Congeria and Mecoliotia, new to Australia, as well as sundry small forms of Pyrgulina, Crossea and Liotia, new to science.

DIARY OF SOCIETIES.

THURSDAY, MAY 22.

INSTITUTION OF ELECTRICAL ENGINEERS (Society of Arts), at 8.—Annual General Meeting.

FRIDAY, MAY 23.

ROYAL INSTITUTION, at 9.—The Ethical Element in Shakespeare: Rev. Canon Ainger.

THURSDAY, MAY 29, 1902.

THE SUPPLEMENT TO THE ENCYCLOPÆDIA BRITANNICA.

Encyclopaedia Britannica. Vol. xxv. Pp. xiii + 786. (Aachen to Australia.) Edited by Sir Donald Mackenzie Wallace, K.C.I.E., K.C.V.O., A. T. Hadley, President of Yale University, and Hugh Chisholm, B.A. (London and Edinburgh: A. and C. Black; London: The *Times* Office, 1902.)

THE critical student familiar with the ninth edition of the "Encyclopædia Britannica" would have no difficulty in detecting a change of intellectual attitude upon examining the volume before us. When the articles were prepared for the ninth edition, in the seventies and eighties of last century, scholastic traditions had a greater influence in determining the point of view than they have to-day. The result was that early periods of history and early developments of the arts and sciences received far more attention than modern views and methods. The significance of the present was disregarded in the contemplation of the past, while the promise of the future was mostly left out of consideration altogether. This retrospective spirit pervaded very many of the articles, and may be said to represent the characteristic style of a generation educated upon literary ideals. Knowledge was regarded as a structure to be observed in various aspects—as material for philosophy—rather than as something to which continual additions should be made, which alter the character of the whole edifice.

Many changes have occurred during the quarter of a century which has elapsed since a large part of the ninth edition was written. The centre of gravity of the intellectual world has for some years been changing its position, and is now much closer to science than it was, though the humanities have not ceased to exert their influence against the movement. There is still a strong disposition to resent any attempt to disturb a balance which has been preserved for so long. Science is considered as a useful servant, which adds to the comforts of life by the practical applications to which it leads, but the pursuit of natural knowledge is not usually considered so dignified and inspiring, or worthy of honour, as art, or literature, or music. In fact, science in England is a drudge to be tolerated, but her pretensions to a position upon the councils of State, or to rank among essential subjects in education, are scarcely countenanced. A man ignorant of the elements of science, and contemptuous of the value of the study of nature in the formation of character, may, even in these days, arrogate to himself the right to define its limits; and he may depend upon the support of all who wish to preserve the old studies from the influence of the progressive school. It is the familiar story of conflict between old and new knowledge, or, to use another simile, between ancient and modern faiths. The priests of the traditional shrine look with disdain upon the altar erected to science, and warn orthodox worshippers against its influence. But mental developments create new attitudes of mind, and unless the guardians of ancient views adapt themselves to new circumstances, they are in opposition to the whole spirit of progress.

In the new volume of our national encyclopædia, it is satisfactory to observe the change that has occurred to bring the work in touch with current scientific results and opinions. The articles upon scientific subjects are numerous, as well as being substantial statements upon the state of various branches of natural knowledge—from the points of view both of the student and the practical man. Among the subjects dealt with are every important country or region with names between Aachen and Australia; in addition to accumulators, acetylene, achromatic objectives, acid and alkali manufacture, acoustics, Adams, adulteration, aëronautics, æther, agriculture, agricultural machinery, air-gun, Airy, algæ, algebra, algebraic forms, alloys, aluminium, amphibia, amphioxus, anatomy, angiosperms, antelope, anthozoa, anthropology, anthropometry, appendicitis, aquarium, aqueduct, arachnida, argon, armour, assaying, astronomy and atmospheric electricity.

It will easily be understood that adequate notice of these contributions could not be given in a review; so all we can do is to describe a few of the subjects surveyed.

The ten pages devoted to "Accumulators" contain a clear account of the principles and structure of several typical cells. In an excellent section on the setting up, forming and discharge of cells (p. 29), the word "hygrometer" is an obvious mistake for "hydrometer." Failures, their remedy and avoidance, are illustrated from a number of charge and discharge curves from actual experiments. The chemical reactions receive due attention, and, finally, the uses of cells in central station work and trams are shortly discussed. It is, however, surprising to find no mention of Salomon's work in the references to the literature of the subject.

Under "Acetylene," a concise account of the stability of the gas under various conditions is followed by a short description of the "ingot" and "run" methods of making carbide, a good *résumé* on the purification of the gas, and a few words upon generators and burners, which might with advantage have been extended.

A short article on "Achromatic Lenses" mentions the recent success of Jena glass and Abbe's experiments.

Under "Acid and Alkali Manufacture," in addition to the well-worn description of sulphuric acid plant, we find an interesting account of the "contact" method for producing SO_3, followed by some details upon the condensation of hydrochloric acid from the salt cake process, and subsequently some valuable judicial statements upon the position of the Leblanc process and the inroads of electrolytic methods.

Under the heading "Acoustics," we have an investigation of the change in form of sound waves of finite amplitude, effects of temperature and wind, short descriptions of König's tuning fork, McLeod and Clark's stroboscopic methods and Lord Rayleigh's phonic wheel, the electrically maintained tuning fork, sensitive flames and jets. Brief investigations are given of Fourier's theorem and the methods of determining the specific heat ratio of air from the velocity of sound. The section on combination tones is of special interest in connection with recent researches.

The article on "Aëronautics" is of especial interest in connection with modern experiments, both on the

propulsion of balloons and on flight proper. It is illustrated by excellent photographs of both Zeppelin's and Santos Dumont's machines, and contains valuable statistical information in the form of tables, which will enable the reader to compare at a glance the means employed and the results achieved in attempts to navigate the air both by the *plus léger* and the *plus lourd* methods. A remarkable result shown by the tables is the very great advance made in increasing the weight sustained per horse-power in the gliding experiments under gravity made by Lilienthal, Pilcher and Chanute, though the writer of the article expresses the opinion that the substitution of an artificial motor would reduce these results by one-half. Another table gives the resistance of surfaces at different incidences, calculated for planes by Duchemin's formula and for curved wings from Lilienthal's investigations; and among other features we notice illustrated accounts of Chanute's gliding machines, Langley's and Hargreaves' aërodromes, and Ader's "Avion." With such information the reader will have little difficulty in forming a correct estimate of the present state of aërial navigation.

It is difficult to summarise briefly the contents of the important article on "Æther." The necessity for assuming the existence of an æther, the differences between æther and matter, the question as to whether the æther is in motion and the dynamical theories of the æther form the chief themes of the article. At the present time "æther" has become an every-day word, but few who use it have much idea of what it means. The present article is clear and authoritative, and if it does not answer the unanswerable question, "What is æther?" it does much to place this question on a sound and scientific basis.

The article "Agriculture" deals, in two separate chapters, with the changes that the past quarter century has witnessed in British and American agriculture, and its most remarkable feature is the contrast which these two chapters present. The first begins with the observation that the period 1875–1900 was a "fateful" one for the "greatest British industry," and in the opening pages shows that floods and stock diseases characterised the first, and drought the last decade of this period; that for every 100 acres under wheat in 1875 there were but fifty-four in 1900; that wheat worth 45*s.* per quarter in the former year was worth 27*s.* in the latter, and that two Royal Commissions investigated the distressed condition of the British farmer. Passing from this melancholy narrative to the chapter on agriculture in the States, we find the American writer revelling in the resources of his country. Between 1875 and 1897 the States farmer took possession of as much new land as would cover all France and Germany.

"Since 1870 the production of nearly all farm crops increased more rapidly than the population, the most absolute proof of the prosperity of the people."

As a result of better implements and better tillage, the yield of wheat is gradually increasing, and will, it is believed, continue to increase. Much land is yet available for wheat-growing, and the idea that a generation hence Americans will cease exporting wheat is regarded as quite erroneous.

The illustrations of British live stock are excellent, and the specimens the photos of which are given prove that "depression" has not yet succeeded in wresting from our breeders the preeminent position they held when the ninth edition was published. We are proud of our draught horses and we congratulate ourselves on their increase; but so different is the American standpoint that the writer almost apologises for their presence.

"Until the use of more and cheaper motors becomes possible, farm animals must increase with farming operations."

It is significant in this connection that all the illustrations of animals are British and all the illustrations of machines American. Some of the implements shown are popular in this country, and some of them are largely manufactured here, but though the workmanship is British the ideas are exclusively American.

Agricultural education and research are actively carried on in the States; on research alone nearly 700 workers are engaged. The English writer describes the work done at Rothamsted, "the greatest and the oldest of experiment stations"; but Lawes and Gilbert are dead and there is no mention of progress. Are we standing still? The writer of the article "Agricultural Machinery" prefaces his chapter by remarking that Americans, as implement makers, have gone "far ahead" of their rivals in the United Kingdom, and "the following article is accordingly written from an American standpoint." The volume does not inspire much hope, but hope and work we must if the next edition of the "Encyclopædia Britannica" is to deal with agriculture from a *British* point of view.

Among the contributions on botanical subjects, the article on the "Algæ" is eminently satisfactory, not only as regards the array of facts, but also as incorporating the results of recent researches and the modifications in arrangement derived therefrom. The connection of the Cyanophyceæ with the Schizomycetes and the relationship of the Diatomaceæ to the Peridiniaceæ are pointed out. Evidence for and against alternation of generations is fairly weighed up, while on polymorphism the conservative view of Klebs is maintained. The physiological principles underlying "Anatomy" are clearly brought out in dealing with non-vascular plants. But when the writer elaborates the stelar conception in connection with vascular plants these principles fall into the background. A tolerably safe course is steered through stelar difficulties, but no attempt is made to separate purely topographical changes from those of a morphological nature. The "Angiosperms" are treated almost entirely from the physiological point of view. Autotrophic plants are described as geophytes, aërophytes and hydrophytes. The author's views on phylogenetic relationships would have been extremely interesting, but discretion overrules speculation. The systems of Bentham-Hooker and Engler-Prantl are merely outlined, while van Tieghem's novel classification is shortly criticised.

The article upon "Universal Algebra" gives in three pages a summary account of the various special algebras which have been invented by modern analysts. Such, for instance, are Hamilton's calculus of quaternions, Grassmann's extensive calculus, and the barycentric calculus of Möbius. The article on "Algebraic Forms"

occupies thirty-seven pages, and is divided into sections dealing respectively with determinants and elimination, symmetric functions, binary and other forms, enumerative functions with their generators, and the theory of restricted substitutions. For the first time, perhaps, the methods of the English school have been discussed, in the same work, in conjunction with the symbolic calculus of Aronhold and Clebsch. Each method has its own special advantages, and the comparative study of both is very instructive. A good deal of space is devoted to Gordan's important theory of transvectants and their reduction, and to Stroh's recent extension of symbolic methods. Many parts of the article illustrate the value of the partition analysis as developed by MacMahon; what he calls "the theorem of expressibility," and the correspondence which he establishes between differential operation and partition operators, are real and fruitful contributions to mathematical science. This article is valuable, not only as a record of known facts, but also as suggesting new fields of research. The section on determinants contains little, if anything, that is not in the text-books; if this had been suppressed, and some other topics treated at greater length, it would have been an advantage.

"Astronomy" occupies twenty-eight pages, which contain a general account of some recent developments relating to the solar system, gravitational and theoretical astronomy, and the sidereal universe. In the section upon the planets, descriptions are given of progress in such subjects as the rotation periods of Mercury and Venus, the markings on Mars, the minor planet Eros, new satellites of Jupiter and Saturn, and Keeler's proof of the discrete constitution of Saturn's rings. The view that the dark regions on Mars are not oceans, as was formerly supposed, but the solid surface of the planet, is accepted, and also that which regards the canals or channels as not being physically continuous formations, but optical effects produced by more or less irregular differences in the minute shadings and colour tints on the surface of the planet.

In the section on gravitational and theoretical astronomy, the chief advances recorded relate to apparent deviations from the law of gravitation exemplified by motions of the planetary perihelia and inequalities of the moon's mean motion, and variation of latitude. The application of photography to celestial portraiture is briefly dealt with in the section on the fixed stars, and it is suggested that what is now required is a photographic survey of the heavens with the view of determining all the stars which have an appreciable parallax. Special attention is given to the structure of the sidereal universe and to systems of stars and clusters, but very little is said of spectroscopic advances in either connection. As progress in astronomy during the last quarter of a century means to a large extent progress in astrophysics, which depends almost entirely upon the spectroscope for its development, we assume that spectroscopic astronomy will be dealt with separately. The article certainly does not convey an accurate or adequate view of the physical and chemical aspects of the science, and it must be supplemented by one on celestial spectroscopy if the complete work is to be regarded as worthy of the intentions of the editors.

To everyone familiar with astronomical progress during the past quarter of a century, the article will be disappointing; for it is more of the nature of an essay than a contribution to an encyclopædia. What is required in an encyclopædic article upon any science is a concise and unbiassed summary of work and results, otherwise the contribution is misplaced. Measured by this standard, the article on astronomy fails entirely of its purpose, for it is both prolix and incomplete. Many small text-books contain far better statements of the position of astronomical science than is here given, because the authors have been to the trouble to become acquainted with the literature of the subject. This, however, has evidently not been done by the writer of the article under notice, and the result is a contribution which will give readers very imperfect ideas as to progress made since the contribution for the ninth edition was written. The new edition of the encyclopædia afforded an opportunity for giving a view of the vast amount of new material which has been accumulated by astronomers from unlooked-for sources, but instead of this inspiring survey we have a superficial essay upon a few points which have appealed to the writer. The article should have been a record of all essential advances of the science, whereas it is more remarkable for what is omitted than for what is included.

Few articles in the ninth edition of the encyclopædia could have required more extensive revision and addition than those devoted to zoological subjects. How great was the need for such revision, and how marked has been the progress in zoological discovery since the appearance of the former edition, is manifest by the articles in the volume under notice, which include the subjects "Amphibia," "Amphioxus," "Anatomy," "Anthropology," "Arachnida" and "Arthropoda." Some of these are in great part practically new treatises, while others, such as the one on anthropology, confine themselves to the additions necessary to bring their predecessors up to date. The change of view that has taken place with regard to the relationships of the lower vertebrates will be manifest when the new and the old articles on amphibia are contrasted, while the advance in our knowledge of the structure of the extinct representatives of the latter is apparent by the amount of space allotted to this portion of the subject. The article on Amphioxus is entirely new, and occupies nearly four pages.

The discoveries of modern histological methods of investigation are fully recorded under the heading of "Anatomy," while the Pithecanthropus is alluded to under "Anthropology," and Mr. Henry's method of classifying finger-prints receives mention in the article "Anthropometry." The Funafuti boring and the inferences to be drawn therefrom are discussed in some detail under "Anthozoa"; while in "Arachnida," Prof. Ray Lankester adduces a long string of facts to show that the nearest living relatives of kingcrabs and trilobites are scorpions rather than crustaceans. Several of the authors had by no means an easy task before them in bringing up to date the work of their predecessors, but they all seem to have done their parts in a highly satisfactory manner.

Finally, we may say that an earnest endeavour has been made by the editors to produce a work which represents the

advances of science since the ninth edition was prepared, in so far as they come within the purview of the present volume. Whether considered as one volume of a supplement to the ninth edition or as a statement of the position of many scientific subjects, the work is a worthy addition to our national literature.

PRACTICAL PHYSIOLOGY.

Directions for Class Work in Practical Physiology. Elementary Physiology of Muscle and Nerve and of the Vascular and Nervous Systems. By E. A. Schäfer, LL.D., F.R.S. Pp. 76. (London: Longmans, Green and Co., 1901.) Price 3*s*. net.

THE contents of this book are well-nigh sufficiently indicated by its subsidiary title, and it is inconceivable that in dealing with the elementary aspects of the subjects named its distinguished author could go wrong. He informs us that his directions are based upon an experience of many years in University College, London, and that they deal "only with such elementary exercises as can readily be worked out by even a large class."

There are twelve chapters in all, and the most distinctive feature of the book is the manner in which the student, having been given concise instructions as to the nature and mode of utilisation of apparatus, and of preparation of the organic object to be studied, is left to "notice" or observe for himself the nature of the effect of this or that operation. A most wholesome procedure—a method of the kind which must be always begotten of a lengthy teaching experience such as the author proclaims.

Of the twelve chapters, the first opens with a description of the "voltaic element" and of the Daniell cell, the rationale of the replacement of the former by the latter being clearly explained. The Grove and Leclanché cells, with the chief types of the latter, are in turn considered; and, with adequate descriptions of electrodes, keys, rheochords, the induction coil and their uses, and a section on unipolar induction, the chapter closes. Chapters ii. and iii. are devoted to nerve-muscle preparations, the sartorius being utilised for the demonstration of the independent irritability of muscle and nerve, and the hyoglossus for that of the "latent period." The effects of heat and cold, of fatigue, the action of curari and veratrin, are in due course considered and clearly set forth; and in chapters v., vi. and vii. the effects of successive stimulation, leading up to tetanus and the muscle sound, the rate of the nervous impulse, the effects of CO_2 and the "electrotonus" phenomenon, are simply described, Ritter's and Pfluger's laws being incidentally laid down.

Chapter viii. deals with secondary contraction and the use of the capillary electrometer and galvanometer. The two chapters which follow are devoted to the heart, cardiac nerves, and the use of the plethysmograph; and the two which conclude the work deal with the chief vascular and respiratory mechanisms in man, with reflex action and its time limitations, as determinable by the use of the Wallerian lever apparatus.

There are in all forty-five simple text-illustrations, thirty-eight of apparatus and seven of dissections of the common frog. The book is well worthy its aim, and Prof. Schäfer, clearly of a mind to give the elementary student little and good, has done that functionary a great service.

There are, in addition to the seventy-six printed pages, twenty-six which are blank; but whether, according to the bookbinder's custom, these are intended to give stability to an otherwise thin volume, or whether they are for the convenience of the student in making annotations, we are not informed. As matters now progress, however, in electrophysiology, it would seem that ere long one or two of these blank pages may be destined to bear a thirteenth chapter, since the Eastern mind, coming fresh and untrammelled to the work, is showing us that under a mechanical stimulus phenomena of electrical response akin to those until recently demonstrated only for the higher animals and the sensitive plants, appear to be at least also obtainable from vegetable organisms at large—a result which points to the conclusion that in these well-known phenomena we are dealing with a fundamental property of protoplasm, and calls for immediate investigation of the unicellular organisms, in the study of which the clue to all that is physiological has ever to be sought.

OUR BOOK SHELF.

The Elements of Physical Chemistry. By J. Livingston R. Morgan, Ph.D. Second edition. Pp. x + 352. (New York: Wiley and Son; London: Chapman and Hall, Ltd., 1902.) Price 2 dollars.

To write a book the object of which is to present the elements of the entire subject of physical chemistry, together with the important and but little known applications of it to the other branches of chemistry, within the scope of 322 small pages is by no means an easy task. The author has, however, succeeded in presenting within these limits a very readable account of the subject.

To the reader familiar with the works on physical chemistry and electrochemistry published by German authors during the last ten years, a close likeness between these and the present volume is at once apparent. The author, as a matter of fact, in his preface states that no claims of originality are made for the major portion of the text.

It is doubtful whether a text-book which is obviously intended for the use of comparatively elementary chemical students should be so replete with mathematical formulæ. For a beginner, a more descriptive method of treatment of the subject would have been, in the opinion of the reviewer, more satisfactory.

The subject-matter is divided into ten chapters, the first being devoted to introductory remarks on the subject of energy and methods of determining atomic weights; then follow sections on the gaseous, liquid and solid states, solution, thermochemistry, chemical change, phases and electrochemistry, the last chapter containing a series of 156 problems bearing upon the subject-matter of the text. This last chapter is a most welcome innovation. For the beginner, the very numerous and abstract formulæ of physical chemistry have but a vague significance; only when these formulæ have been applied to concrete cases do they become properly understood by the student. Ample scope for exercise in the application of these formulæ is provided by the last chapter, although perhaps in a few cases the problems are not very happily chosen.

Thermochemistry and the phase rule are treated of in a superficial manner, only five pages being devoted to the consideration of the latter. In a future edition it is hoped that the author will see fit to deal with the important work which has been done on transition tem-

peratures and the formation and decomposition of double salts. Although the present volume is a second edition of the work, yet the text is not free from misstatements. On p. 87 we are told that "when liquids mix in all proportions . . . then it is possible to make a complete separation of the constituents by a fractional distillation, provided the vapour pressures of the two differ," a statement which is afterwards contradicted by examples which are given of the different types of liquid mixtures. On p. 210 we are told that the ferrous ion is greenish-black in colour, and on p. 260 that all binary organic acids satisfy the dilution law of Ostwald. Misprints are also not uncommon and authors' names are not always correctly spelt, "Tammen" for "Tammann" and "Pebel" for "Pebal" being instances.

If, however, the defects here alluded to are remedied in the next edition, the book will, without doubt, serve as a very useful aid to students of physical chemistry.

H. M. D.

Practical Botany for Beginners. By F. O. Bower, Sc.D., F.R.S., and Dr. T. Gwynne-Vaughan, M.A. Pp. xi + 307. (London: Macmillan and Co., Ltd., 1902.) Price 3*s.* 6*d.*

This excellent little book, written by Prof. Bower in 1894, appears in a second edition after being subjected to careful revision. Mr. Gwynne-Vaughan now shares with Prof. Bower the author's responsibility. The more prominent changes are the adoption of the nomenclature introduced with the stelar conception and a more elaborate description of grosser morphological features. The number of seeds described is increased to eight Dicotyledons and three Monocotyledons, and more than twenty flowers are taken as types of these two groups. The main types remain the same, except that the elm gives place to the lime. Other additions are the stems of Ricinus, *Veronica Beccabunga* (aquatic Dicotyledon), *Elodea Canadensis* (aquatic Monocotyledon), and leaves of Ligustrum, Hedera, Deschampsia and Phormium. The paragraphs on reserve and transitory materials have been considerably added to and improved, so that suitable material and the necessary tests are given for demonstrating the presence of starch, proteids and various sugars in the vegetative parts and in seeds. Exception may be taken to certain types chosen—for instance, Marchantia and Fucus—but obviously the general occurrence of these has weighed with the authors in their choice. Passing to methods of manipulation, glycerine and chlor-zinc iodine are almost exclusively recommended as mounting media; in several cases, notably Pinus, double staining and mounting in Canada balsam would give better results, while mounting in water avoids undue swelling of the walls of phloem cells such as follows the use of glycerine and Schulze's solution.

The book is already so well known that it is unnecessary to emphasise the careful arrangement of subject and the clear descriptions which characterise it.

Quelques réflexions sur la mécanique suivies d'une première leçon de Dynamique. Par Émile Picard, Mem. Inst. France. Pp. 56. (Paris: Gauthier Villars, 1902.)

The first part is based on a report drawn up by M. Picard in connection with the Paris Exhibition of 1900 dealing with modern views on the principles of mechanics and in particular on the "energetic" method, and the dynamical system of Hertz. The second part consists of the first lecture given by M. Picard, since 1894, in his course on general mechanics, introducing the elementary principles of dynamics. It differs somewhat from the conventional treatment, and in this country Newton's third law will probably be regarded as constituting a less artificial definition of *mass* than is used by M. Picard.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Volcanic Eruption in Java, Brilliant Sunset Glows in 1901, and probable Glows from the Eruption in Martinique.

The brilliant sky glows and sunsets following the eruption of Krakatoa, near Java, on August 26 and 27, 1883, threw a flood of light on the movements of the upper atmosphere in a way which was probably not otherwise possible. Up to that time it had been supposed generally by meteorologists that the air forming the trade winds ascended at the equator and turning toward the poles became a south-westerly current in the northern hemisphere and a north-westerly current in the southern hemisphere flowing over the trades. After the explosion eruption of Krakatoa, the large mass of observations gathered by the committee of the Royal Society and the admirable discussion of the optical phenomena by Russell and Archibald ("The Eruption of Krakatoa and Subsequent Phenomena," London, 1888) brought out the following facts:—

(1) The haze, sky glows and brilliant sunsets progressed from east to west three times around the world within the tropics at a rate of about seventy-five miles an hour.

(2) They spread northward and southward from 20° N. and 20° S. very slowly, taking from September 2 to about October 7 for the conspicuous phenomena to spread from 20° N. to 35° N. in America, a velocity of about one-half a degree a day, or one mile an hour.

(3) Above 35° latitude the progressive motion was rapid and apparently from the south-west in the northern hemisphere and from the north-west in the southern hemisphere.

There are two other important conclusions which I think may be drawn from the data, and these are:—

(1) The atmosphere between 20° N. and 20° S. moved with a nearly uniform velocity from the east; otherwise it would have been impossible to trace the movement of the dust cloud around the world three times, because a very slight difference in velocity or direction at different latitudes would very soon have destroyed the individuality of the cloud, whereas Russell's lines of first appearance are nearly parallel with each other between 20° N. and 20° S.

(2) There are frequent temporary disturbances in this region by which the air is carried rapidly outward in narrow belts into extratropical regions. One of these disturbances was shown on August 27, when the dust was carried rapidly to Japan, another on August 28, when dust was carried to South Africa, and another on September 1, when dust was carried to Santiago, Chili.

The movement of the atmosphere above the tropics established by this investigation differed so from that supposed to exist by meteorologists that it was sought to explain it as a temporary movement and not representative of average conditions. But Abercromby was so much impressed by the phenomena that he began to gather observations of the movements of cirrus within the tropics. These are published in the volumes of Nature between 1887 and 1890. Hildebrandsson has pursued the subject farther, and his results show that in the equatorial regions between 20° N. and 20° S. the prevailing movement of the cirrus is from the east. North and south of these latitudes the directions change to a movement from the west. It is probable that between these two opposing belts of wind there is a nearly calm zone across which the air movesf very slowly from the equator.

These facts are dwelt on in order to show the importance of such observations preliminary to calling attention to recent sky glows and volcanic eruptions.

In the autumn of 1901, Mr. Rotch, Mr. Sweetland and myself noticed independently that the sunsets were more brilliant than usual at Blue Hill (lat. 42° 13′ N., long. 71° 7′ W.), and the following notes were entered in the records of the Observatory:—
"October 7.—Since about September 20 the sunsets on clear days, including to-day, have shown unusually bright colours, a bright red predominating and lasting near the horizon for three-quarters of an hour or longer; November 2, a very brilliant sunset, red prevailing, and the colours continued for about forty-five

minutes after sunset; November 3, a brilliant orange sunset after a very clear day."

These observations were recalled by the receipt within a few days of a pamphlet from Mr. T. F. Claxton on "The Recent Sunset and Sky Glows." This paper was presented to the Mauritius Meteorological Society on August 27, 1901.

The first few paragraphs are as follows:—

"The gorgeous sunsets and sky glows of the past three months recall those vivid displays of 1883 and 1884 which were associated with the disastrous volcanic eruptions at Krakatoa, in the Straits of Sunda, and it is not surprising to learn that toward the end of May of this year similar, though less serious, eruptions occurred in about the same locality, according to the following cablegram which appeared in the *Daily Graphic*:—

"'Batavia, *May* 23, 1901.—The volcano of Keloet is in eruption. It is reported that there has been great loss of life among the natives. District of Kediri enveloped in total darkness.'"

The sunset glows at Blue Hill followed this eruption, and the sky glows at Mauritius after about the same interval as similar but more brilliant glows in these latitudes followed the eruption of Krakatoa. It would be extremely interesting to know if there are observations at intervening places. We should be glad to receive notes of such at the Blue Hill Observatory, Hyde Park, Mass., U.S.

I wish also to call attention to the recent violent volcanic eruption in the island of Martinique, and suggest that observers be on the watch for the earliest optical phenomena. We should be glad to receive notices of such observations. There were some marked barograph undulations at Blue Hill on the morning of May 7 which are perhaps connected with this volcanic eruption. HENRY HELM CLAYTON.

Blue Hill Observatory, Hyde Park, Mass., May 10.

A Method of Showing the Invisibility of Transparent Objects under Uniform Illumination.

As is well known, a perfectly transparent object is visible only in virtue of a variable illumination. This condition might be approximately realised, as Lord Rayleigh points out in his article on "Optics" in the "Encyclopædia Britannica," on the top of a high monument in a dense fog. It is doubtful, however, if the experiment would be very successful even under these conditions, as the observer's body screens the light in certain directions, making the illumination far from uniform. The following method I have found to give very good results:—

The inside of a hollow sphere of metal, which can be separated into two cups, is thickly coated with Balmain's luminous paint. A small hole, not much larger than the pupil of the eye, enables the observer to view the interior and any objects within the sphere. I used for the sphere one of the metal floats which are used as automatic regulators in water tanks, and which can be obtained from any plumber. The float was made in two parts, which were easily separated by melting the solder. It is rather difficult to get a good uniform layer of the paint. Several coats are required, and even then it is apt to appear streaky in the dark. I am inclined to think that a better plan would be to mix the dry powder with boiled down Canada balsam, which will harden on cooling, and coat the outside of two glass hemispherical evaporating dishes with the hot mixture. The lips of the dishes would make the eye-hole. This mixture I have found produces much more uniform surfaces, and I am employing it at the present time in some experiments in infra-red photography.

If the inner surface is exposed to sunlight, and a transparent object such as a glass or crystal ball, a thick lens or a cut glass decanter stopper is put in the interior, it will be found to be practically invisible when viewed through a small hole, for light of equal intensity is incident in every direction. I have found that a large stopper with many facets does not quite disappear, some of the edge facets appearing darker than the diffused blue glow which fills the interior of the ball. This I believe to be due to the fact that the light reaching the eye from these facets by refraction happens to have undergone several internal reflections and suffered a loss by absorption owing to a long path through the glass. The luminosity of the interior of the sphere is not quite uniform, however, and this may be sufficient to explain the appearance of these facets. The observation is best made in a darkened room, the eye being brought close up to the small aperture.

Since writing the above I have tried the balsam mixture on the outside of hemispherical glass dishes. It is, however, better to scratch a small hole in the paint than to attempt to use the lips of the dish as an aperture, as in the latter case the line of union, which is always slightly darker than the rest of the surface, cuts directly across the field of view, which is a disadvantageous arrangement. R. W. WOOD.

Johns Hopkins University, Baltimore.

Misuse of Coal.

THE tone of Prof. Perry's letter in reply to Mr. Rosenhain is so acquiescent that it may seem to diminish the force of his original contention as to the national misuse of our stock of coal. There are two considerations which ought to be stated in reply to the plea that men may learn to grow their fuel as they go on, by a proper cultivation of the best vegetation.

The first is this. The soil will not long continue to yield food if it be asked to provide fuel also. About three years ago Sir W. Crookes devoted his address, as president of the British Association, to the consideration of the present position of the world's food-supply question, and arrived at the conclusion that the outlook was not far from a gloomy one.

In that conclusion he was but echoing Malthus, though with much better data and a more complete record as to what were in Malthus' day unexplored countries.

If examination of the food-yielding powers of the soil leads to such a result, it is evident that to add an additional demand for fuel will seriously injure both. Even though Malthus and Sir W. Crookes be only partially right, enough is left to prevent us getting any long-lived satisfaction by growing fuel. There remains the possibility of "intensive" cultivation, and this may be one form of the new engine Prof. Perry asked scientific men to look for. Already Lord Rayleigh has made a bold attempt to make this economically possible by preparing nitric acid from the air. Perhaps with the resources Prof. Perry asked for, Lord Rayleigh might succeed.

The second point is this. Prof. Perry's concern was mainly for British resources. The economic life of a large proportion of our people is bound up with an economic advantage in fuel and other minerals. Every scientific discovery which raises the efficiency of transformation from coal fuel to mechanical power helps to defer the day in which England's mineral endowment will no longer be exceptional. The moment that oil or other natural fuel can compete with coal in the open markets, our prosperity must begin to decline. Similarly, if fuel can be grown to compete with coal, we lose position, simply because we cannot expect to grow so easily and well as many other countries.

The motive impelling towards a constant search for improved efficiency in the use of coal is therefore doubly strong on our people and Government. Any improvement would be helpful to the whole world; for us it would defer a calamity, possibly for a very long time. W. HIBBERT.

The Conservation of Weight and the Laws of Thermodynamics.

IN NATURE of May 15, Lord Rayleigh uses the laws of thermodynamics to prove the conservation of weight.

In regard to the doctrine of the conservation of energy (the first law of thermodynamics) the following statement is made in Maxwell's "Theory of Heat," p. 145, tenth edition: "The evidence which we have of the doctrine is nearly if not quite as complete as that of the conservation of matter."

Taking this passage to imply that the two doctrines, conservation of weight and of energy, are to be held true as far as experiment has proved them true, and no farther, the question arises—To what extent have the laws of conservation been proved?

The experiments of Landolt (1893) and of Heydweiller (1901) show that the conservation of weight holds, in the cases investigated by them, to one part in one hundred thousand. The accuracy of the law to one part in a million is left under suspicion.

Energy being more difficult to measure than weight, it is unlikely that the conservation of energy has been proved to one part in one hundred thousand. At the present time, would not Maxwell say, "The evidence which we have of the conservation of energy is not as complete as that of the conservation of weight"?

From the laws of thermodynamics it can be shown, doubtless, that the conservation of weight is absolutely true, but this only on the assumption that the conservation of energy is absolutely true. Again, granted it can be shown that the conservation of weight is true in the same degree as the conservation of energy, yet these proofs will remain of strictly mathematical interest so long as our knowledge of the conservation of energy remains of a lower order of accuracy than that of the conservation of weight.

It seems natural for the human mind to state scientific laws in absolute terms. Nevertheless, in most cases it is proved that the accuracy of the laws is limited. If a scientific law is believed in outside the limits of proof, the law is no longer a matter of knowledge—it has become an article of faith. These are platitudes; they have point only because scientific men state the laws of conservation in absolute terms, and hold these laws as articles of faith. A. N. M.

University College, Liverpool.

A Solar Halo.

IN a letter to NATURE of May 1 (p. 5) a description is given of a remarkable lunar halo seen at Yerkes Observatory. A solar halo of almost identical character is reported in the meteorological returns for April from Sule Skerry Lighthouse off the north coast of Scotland. The following note and sketch are appended by Mr. N. A. Macintosh, the lightkeeper, to his report:—

"A curious phenomenon was observed in the sky on the 28th. At 12.30 p.m. there was a perfect ring or halo right round

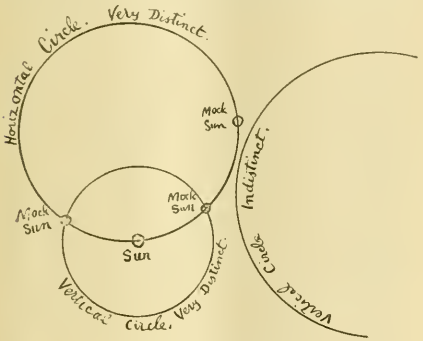

FIG. 1.—Solar Halo, April 28.

the top of the sky with the sun in its southern edge. At right angles to it, and round the sun, was another ring with two 'mock suns' where it bisected the larger ring. These 'mock suns' showed prismatic colours, but about due east on the edge of the larger ring there was a 'mock sun' pure white. In the south-eastern sky there was an indistinct half-circle from the horizon up to the horizontal circle which showed prismatic colours, whilst the others were colourless. At the time there was haze all over the sky, but the sun shone very clearly. It lasted till 1.30 p.m."

The position of Sule Skerry is lat. 59° 6′ N., long. 4° 20′ W., and as the sun is about 14° north of the equator on April 28, its elevation at local noon, about which time the halo was first seen, would be practically 45°. Hence the "horizontal circle" the centre of which is at the zenith would have a radius of 45°. Evidently, therefore, from Mr. Mackintosh's sketch the "vertical circle" is the ordinary halo of 22° radius. The "horizontal circle" is also well known, though not so often seen as the halo; it is due to the reflection of the sun's light from the vertical faces of the ice-crystals. The coloured mock suns where the two halos intersect are also well known, but with the sun as high as 45° they would be expected to lie a little outside the 22° halo on the white circle. The other mock sun on the eastern side of the horizontal white circle is more rare; it may coincide with the point where a larger halo cuts the horizontal circle, but the laws determining the formation of this halo and its exact position are not known, and portions of it have been seen on only three or four occasions of which we have any record.

The last item in the sketch, the coloured semicircle rising from the south-eastern horizon to almost touch the horizontal circle, I am unable to suggest any explanation for. The sketch is evidently reversed, as in it this and the white mock sun are shown on the western side. In recording observations of coloured halos, mock suns, &c., it would greatly add to their values if notes were made of the arrangement of the colours, such as "red inside, blue outside halo," "red next sun, blue away from it," and *vice versâ*. Mathematical Training.

IN view of the great influence which Schopenhauer has exerted on German thought, I referred to his chapter on mathematics, and find that half a century ago he was even more sweeping in his condemnation of the methods of Euclid than are some of your present correspondents. He mentions that the exact sciences are confined to those dealing with time, space and causality, or without being too precise as regards names, the exact sciences are arithmetic, geometry and logic. Schopenhauer's view is that each of these sciences is independent of the other, and he illustrates this by saying that mathematically it is just as self-evident that two parallel lines cannot meet as it is logically self-evident that an impossibility is not possible. He strongly objects to our aping the Greeks and basing mathematics on logic, and I feel sure that he would consider that mathematics were being degraded by the excuse so often given for teaching it at all, that "Euclid is an invaluable logical training." If I understand him correctly, Schopenhauer holds that any mathematical proposition is as self-evident as any correct logical sequence, and only requires illustrations or explanations (not proofs) to make this clear to our somewhat imperfect brain. This he might have illustrated by the Pythagorean proposition, which can be shown to be correct without the elaborate logical scaffolding used by Euclid, provided that one's mind can grasp the proportionality of similar triangles. Let a, b, c be the lengths of the sides of a right-angled triangle, draw a perpendicular from the apex intersecting the hypothenuse c, and divide it into two lengths d and e. We then have three similar right-angled triangles and the following two sets of proportions:—

$$\frac{c}{a} = \frac{a}{e} \text{ and } \frac{c}{b} = \frac{b}{d},$$

from which it follows that $a^2 = c \,.\, e$ and $b^2 = c \,.\, d$, and as $d + e = c$, we have $a^2 + b^2 = c^2$.

Most other propositions, if not self-evident, might be dealt with in the same way; and if we were as gifted as Newton was, we would, as he did, wonder why anybody should trouble to demonstrate the, to him, quite self-evident truths in Euclid.

In our public schools we are taught classics, not because of the logic they contain, for it is often wrong, but because they exercise our memory (and, I fear, cripple our reasoning powers), and we teach mathematics, not to improve our knowledge of space, but to improve our logic and sometimes also to improve our memory. Naturally our views about space are often hazy, and our reasoning powers, which receive no direct training, are not infrequently stunted, or rather compelled to work in narrow grooves. C. E. STROMEYER.

Lancefield, West Didsbury, May 12.

Influence of Light upon Plant Assimilation.

I HAVE for some time been endeavouring to devise a simple and cheap apparatus for demonstrating the effect of red and blue light respectively upon the assimilatory power and nyctitropic movements of plants. The apparatus usually supplied by the dealers for this purpose consists of a double-walled bell-jar into which a solution of potassium bichromate or of ammoniacal copper sulphate may be poured. This is a rather expensive piece of apparatus for school use, especially if a large one is required. I have not been able to find a blue or red glass that absorbs blue or red light only. I have tried home-made glass cells about a foot square and a quarter of an inch internal diameter, but could not prevent leakage. Perhaps some reader of NATURE could help me. Is there a transparent coloured paper or some kind of coloured membrane that would serve the purpose? E. E. HENNESEY.

Bigods School, Dunmow, Essex, May 19.

THE FARMERS' YEARS.

II.

CARNAC AND ITS ENVIRONS.

It has long been known that the stones which compose the prehistoric remains in Brittany are generally similar in size and shape to those at Stonehenge, but in one respect there is a vast difference. Instead of a few, arranged in circles, as at Stonehenge, we have an enormous multitude of the so-called menhirs arranged in many parallel lines for great distances.

The literature which has been devoted to them is very considerable, but the authors of it, for the most part, have taken little or no pains to master the few elementary principles which are necessary to regard the monuments from the point of view of orientation.

It is consoling to know that this cannot be said of the last published contribution to our knowledge of this region, which we owe to Monsieur F. Gaillard, a member of the Paris Anthropological Society and of the Polymathic Society of Morbihan at Plouharnel.[1]

M. Gaillard is a firm believer in the orientation theory and accepts the view that a very considerable number of the alignments are solstitial. But although he gives the correct azimuths for the solstitial points and also figures showing the values of the obliquity of the ecliptic as far as 2200 B.C., his observations are not sufficiently precise to enable a final conclusion to be drawn, and his method of fixing the alignments and the selection of the index menhir is difficult to gather from his memoir and the small plans which accompany it, which deal with compass bearings only.

All the same, those interested in such researches owe a debt of gratitude to M. Gaillard for his laborious efforts to increase our knowledge, and will sympathise with him at the manner in which his conclusions were treated by the Paris anthropologists. One of them, apparently thinking that the place of sun rising is affected by the precession of the equinoxes, used this convincing argument:—"Si, à l'origine les alignments étaient orientés, comme le pense M. Gaillard, ils ne le pourraient plus être aujourdhui ; au contraire, s'ils le sont actuellement, on peut affirmer qu'ils ne l'étaient pas alors !"

M. Gaillard is not only convinced of the solstitial orientation of the avenues, but finds the same result in the case of the dolmens.

I cannot find any reference in the text to any orientations dealing with the farmers' years, that is with amplitudes of about 24° N. and S. of the E. and W. points ; but in diagrams on pp. 78 and 127 I find both avenue and dolmen alignments, which within the limits of accuracy apparently employed may perhaps with justice be referred to them ; but observations of greater accuracy must be made, and details of the heights of the horizon at the various points given, before anything certain can be said about them.

I append a reproduction of one of M. Gaillard's plans, which will give an idea of his use of the index menhir. It shows the cromlech and alignments at Le Ménec. The line A—Soleil runs across the stone alignments and is fixed from A by the menhir B, but there does not seem any good reason for selecting B except that it appears to fall in the line of the solstitial azimuth according to M. Gaillard. But if we take this azimuth as N. 54° E., then we find the alignments to have an azimuth roughly of N. 66° E., which gives us the amplitude of 24 N. marking the place of sunrise at the beginning of the May and August years, and the alignments may have dealt principally with those times of the year.

I esteem it a most fortunate thing that while I have been casting about as to the best way of getting more accurate data, Lieutenant Devoir, of the French Navy, and therefore fully equipped with all the astronomical knowledge necessary, who resides at Brest and has been studying the prehistoric monuments in his neighbourhood for many years, has been good enough to write me a long letter giving me the results of his work in that region, in which the problems seem to be simpler than further south ; for while in the vicinity of Carnac the menhirs were erected in groups numbering five or six thousand, near Brest they are much more restricted in number.

Lieut. Devoir, by his many well-planned and completely accurate observations, has put the solstitial orientation beyond question, and, further, has made a most important observation which establishes that the May and

FIG. 1.—Alignments at Le Ménec.

August sunrises were also provided for by a system of alignments. He permits me to make the following extracts from his letter:—

"It is about twelve years ago that I remarked in the west part of the Department of Morbihan (near Lorient) the parallelism of the lines marked out by monuments of all sorts, and frequently oriented to the N.E., or rather between N. 50° E. and N. 55° E. I had ascertained, moreover, the existence of lines perpendicular to the first named, the right angle being very well measured.

"The plans, which refer to the cantons of Ploudalmézeau and of St. Renan (district of Brest) and of Crozon (district of Chateaulin), have been made on a plane-table ; the orientations are exact to one or two degrees.

[1] "L'Astronomie Préhistorique." Published in "Les Sciences Populaires, revue mensuelle internationales," and issued separately by the administration des "Sciences populaires," 15 Rue Lebrun, Paris.

"In the cantons of Ploudalmézeau and of St. Renan, the monuments are generally simple; seven menhirs are visible of enormous dimensions, remarkable by the polish of their surface and the regularity of their section. The roughnesses hardly ever reach a centimetre; the sections are more often ovals, sometimes rectangles with the angles rounded or terminated by semicircles. In the canton of Crozon the monuments are, on the contrary, complex; we find a cromlech with an avenue leading to it of a length of 800 metres, another of 300 metres. Unfortunately, the rocks employed (sandstone and schist from Plungastel and Crozon) have resisted less well than the granulite from the north part of the Department. The monuments are for the most part in a very bad condition; the whole must, nevertheless, formerly have been comparable with that of Carnac-Leomariaquer.

"For the two regions, granitic and schistose, the results of the observations are identical.

"The monuments lie along lines oriented S. 54° W. → N. 54° E. (54° = azimuth at the solstices for $L = 48° 30'$ and $i = 23° 30'$) and N. 54° W. → S. 54° E. Some of them determine lines perpendicular to the meridian.

"One menhir (A), 6m. 90 in height and 9m. 20 in circumference, erected in the small island of Melon (canton of Ploudalmézeau, latitude 48° 29′ 05″) a few metres from a tumulus surrounded by the ruins of a cromlech (B and C), has the section such that the faces 1 and 2, parallel and remarkably plane, are oriented N. 54° E. (Figs. 2 and 3.)

"At 1300 metres in the same azimuth there is a line of three large menhirs (D, E, F) of which one (E) is overthrown. The direction of the line passes exactly by the menhir A. Prolonged towards the N.E. it meets at 3k. 700m. an overturned block of 2m. 50 in height, which is without doubt a menhir; towards the S.-W. it passes a little to the south some lines of the island Molène. . . . (Fig. 4.)

"There exists in the neighbourhood other groups, forming also lines of the same orientation and that of the winter solstice. It is advisable to remark that orientations well determined for the solstices are much less so for the equinoxes, which is natural, the rising amplitude varying very rapidly at this time of year.

"The same general dispositions are to be found in the complex monuments of the peninsula of Crozon. I take for example the alignments of Lagatjar. Two parallel lines of menhirs, G G′ H H′, are oriented to S. 54° E. and cut perpendicularly by a third line, I I′. There existed less than fifty years ago a menhir at K, 6 metres high, which is to-day broken and overturned. This mégalith, known in the country by the name of 'pierre

du Conseil' (a bronze axe was found underneath it) gives with a dolmen situated near Camaret the direction of the sunrise on June 21.

"I have just spoken of the lines perpendicular to the solstitial one; there exists more especially in the complex

FIG. 5.—Alignment at Lagatjar, G G'.

monuments another particularity which merits attention. Between two monuments, M and N, on a solstitial line, sometimes other menhirs are noticed, the line joining them being inclined 12° to the solstitial line, always towards the east."

I must call particular attention to this important observation of Lieut. Devoir, for it gives us the amplitude 24° N., the direction of sunrise at the beginning of the May and August years. It shows, moreover, that, as at Le Ménec according to M. Gaillard, the solstitial and May-August directions were both provided for at the monuments in the neighbourhood of Brest so carefully studied by Lieut. Devoir.

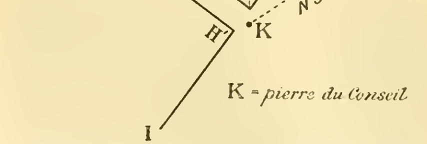

FIG. 6.—Alignments at Lagatjar, showing the pierre du Conseil and the direction of the dolmen. From the pierre du Conseil the dolmen marks the sunrise place at the summer solstice, and the avenue G G' H H' the sunset place on the same day.

I think I have already stated that there is evidence at Stonehenge that the sunrise at the beginning of the May and August years was observed, so that in this we have another point common to the British and Breton monuments.

Lieut. Devoir points out the wonderful regularity of form and the fine polish of many of the menhirs. The one at Kerloas (11 metres high) heads the list in point of size; others in the island of Melon (7 metres), at Kergadion (8 metres and 10 metres), Kerenneur, Kervaon and Kermabion follow suit. He considers them to have been erected at the time of the highest civilisation of the Megalithic peoples. It will be of interest to inquire whether they are generally associated with solstitial alignments. He also states that these regularly formed menhirs do not exist at Carnac, or in the region of Pont l'Abbe, so rich in other remains. It may be, then, that in these localities the May-August worship predominated, and that the index menhirs of M. Gaillard which do not form part of the alignments were erected subsequently.

THE YEARLY FESTIVALS IN EGYPT.

The vague year in Egyptian chronology makes it a very difficult matter to determine the exact Gregorian dates for the ancient Egyptian Festivals, but, fortunately, there is another way of getting at them.

Mr. Roland Mitchell, when compiling his valuable "Egyptian Calendar" (Luzac and Co., 1900), found that the Koptic Calendar really presents to us the old Egyptian year, "which has been in use for thousands of years and has survived all the revolutions."

Of the many festivals included in the Calendar, the great Tanta fair, which is also a Mohammedan feast, "is the most important of all held in Egypt. Religion, commerce and pleasure offer combined attractions." As many as 600,000 or 700,000 often attend this great fair. Mr. Mitchell holds that it is "no doubt the survival of one of the ancient Egyptian national festivals."

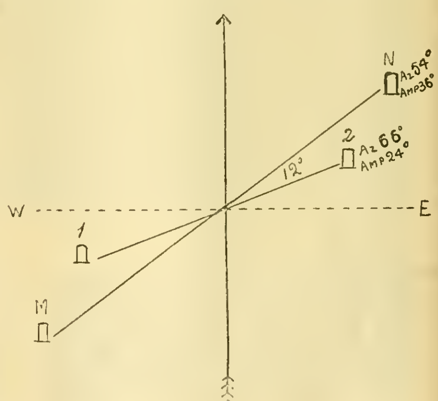

FIG. 7.—Menhirs M, N, on N.E.-S.W. solstitial alignment. Menhirs 1, 2, on May-August years alignment, sunrise May-August, sunset November-February.

It is held so as to end on a Friday, and in 1901 the Friday was August 9!

This naturally suggests that we should look for a feast

in the early part of May. We find the festival of El-Khiḍr and Eliâs in the middle of the wheat harvest in Lower Egypt; of this we read :—

"El-Khiḍr is a mysterious personage, who, according to learned opinion, was a just man, or saint, the Visīr of Zu'l-Karneyn (who was a great conqueror, contemporary with Ibrahīm—Abraham—and identified in other legends with Alexander the Great, St. George, &c.). El-Khiḍr, it is believed, still lives, and will live until the Day of Judgment. He is clad in green garments, whence probably the name. He is commonly identified with Elias (Elijah), and this confusion seems due to a confusion or similarity of some of the attributes that tradition assigns to both."

"The 'Festival of El-Khiḍr and of Elias,' falling generally on May 6, marks the two-fold division of the year in the Turkish and Armenian Calendars, into the Rūz Kāsim and the Rūz Khiḍr (of 179-80 and 185-6 days respectively)."

This last paragraph is important, as it points to ancient sun worship, Helios being read for Elias; and 179 days from May 6 bring us to November 1. So we find that the modern Turks and Armenians have the old May-November year as well as the ancient Egyptians who celebrated it in the Temple of Min at Thebes.

The traces of the Ptah worship are not so obvious. Finally, it may be stated that the second Tanta fair occurs at the spring equinox, so that the pyramid worship can still be traced in the modern Egyptian Calendar. The proof that this was an exotic is established, I think, by the fact that no important agricultural operations occur at this period in Egypt, while in May we have the harvest, in August and November sowing, going on.

THE NEW YEAR'S OFFERINGS.

In my last article I showed that each year, whenever it began, was, if possible, associated with some fruit of the earth, and that at the winter solstice the chief available vegetable product was the mistletoe.

But about the mistletoe there is this difficulty. Innumerable traditions associate it with the Druids and the oak tree. Undoubtedly the year of the Druids was the solstitial year, so that so far as this goes the association is justified. But as a rule the mistletoe does not grow on oaks. This point has been frequently inquired into, especially by Dr. Henry Ball (*Journal of Botany*, vol. ii. p. 361, 1864), in relation to the growth of the plant in Herefordshire, and by a writer in the *Quarterly Review* (vol. cxiv.), who spoke of the mistletoe "deserting the oak" in modern times and stated, "it is now so rarely found on that tree as to have led to the suggestion that we must look for the mistletoe of the Druids, not in the *Viscum album* of our own trees and orchards, but in the *Loranthus Europaeus* which is frequently found on oaks in the south of Europe."

On this point I consulted two eminent botanical friends, Mr. Murray, of the British Museum, and Prof. Farmer, from whom I have learned that the distribution of *V. album* is in Europe universal except north of Norway and north of Russia; in India in the temperate Himalayas from Kashmir to Nepaul, altitude 3000 to 7000 feet.

The *Viscum aureum*, *Viscum luteum* or *Loranthus Europaeus*, according to Dixon,[1] is a near relation of the familiar mistletoe, and in Italy grows on the oak almost exclusively. There are fifty species of Loranthus in the Indian flora, but *L. Europaeus* does not occur.

In the *Viscum aureum* we have the "golden bough," the oak-borne *Aurum frondens* and *Ramus aureus* of Virgil; and it can easily be imagined that when the Druids reached our shores this would be replaced by the *V. album* growing chiefly on apple trees and not on oaks; indeed, Mr. Davies, in his "Celtic Researches," tells us that the apple was the next sacred tree to the oak, and that apple orchards were planted in the vicinity of the sacred groves. The transplanting of the mistletoe from the apple to the oak tree before the mystic ceremonies began was not beyond the resources of priestcraft.

[1] *Notes and Queries*, Ser. iv. vol. iii. p. 113.

It must not be forgotten that these ceremonies took place at both solstices—once in June, when the oak was in full leaf, and again in December, when the parasitic plant was better visible in the light of the young moon. Mr. Fraser, in his "Golden Bough" (iii. p. 328), points out that at the summer solstice not only was mistletoe gathered, but many other "magic plants whose evanescent virtues can be secured at this mystic season alone."

It is the ripening of the berries at the winter solstice which secured for the mistletoe the paramount importance the ceremonials connected with it possessed at that time, when the rest of the vegetable world was dormant.

NORMAN LOCKYER.

THE RECENT VOLCANIC ERUPTIONS IN THE WEST INDIES.

IN continuation of the articles which have already appeared in NATURE upon the recent volcanic disaster in the West Indies, we are able to give this week some further information upon the character and consequences of the eruptions. Prof. Milne traces the development of the disturbances and uses his intimate knowledge of volcanic and seismic effects to show how they may be interpreted. In addition, we give two separate notes upon the ash ejected during the eruptions, and seismographic records in France on May 6. The nature of the dust ejected from the Soufrière will soon be satisfactorily determined, for last week's West Indian mail brought to this country numbers of packets of the volcanic ash which fell at Barbados, 100 miles *to windward*, during the night of May 7-8. The Imperial Department of Agriculture has despatched specimens to the Natural History Museum, the Geological Society, Prof. Judd, &c.

Arrangements have been made for the small scientific expedition referred to in last week's NATURE, and the members are to sail as we go to press with this number. The expedition consists of Dr. Tempest Anderson, Dr. Flett, and another member of the staff of the Geological Survey. The Colonial Office has promised to assist the Royal Society in defraying the expenses of this expedition.

For convenience, we bring together in diary form the reports of volcanic and other possibly related disturbances which have occurred during the past few days. This record of events is in continuation of those already abridged from dispatches published in the *Times*, *Daily Mail*, *Daily Graphic* and other papers :—

May 18, *Autun* (*France*).—Uneasiness is beginning to be felt in regard to the volcano of St. Pierre-de-Varennes, between Couches-les-Mines and Le Creusot, which has always been considered extinct. Low rumblings have been heard, accompanied by tremblings of the earth, and at 11.30 p.m. similar noises of more than usual loudness caused considerable alarm among the inhabitants of the district.

May 18, *St. Vincent*.—An eruption of the Soufrière occurred between about 8.30 p.m. and midnight, accompanied by thundering noises and incessant electrical discharges.

May 19.—There was a great eruption of Mont Pelée. The volume of lava emitted surpassed that of May 8. It overflowed Grande Rivière and destroyed the buildings and cultivation which were previously untouched.

May 20, *Pointe à Pitre*.—Mont Pelée ejected thick black cloud and hot mud and stones, covering the greater part of Martinique. A heavy pall hung over Fort de France, followed by flashes of light.

May 21, *Fort de France*.—A further eruption of Mont Pelée occurred.

May 22, *Victoria* (*B.C.*).—An explosion occurred in the Crow's Nest coal mines at Fernie, in the Kootenay district.

May 22, *Pointe à Pitre*.—From the new crater on the north side of Mont Pelée the lava is flowing in a broad stream into the sea.

May 24, *Fort de France*.—Mont Pelée emitted a torrent of lava and mud, which rushed down the northern slope and swept away what remained of the town of Basse Pointe. New fissures also opened in the side of the mountain.

May 24, *St. Vincent*.—Rumblings are heard and vapour is still issuing from different points on the Soufrière, and lava is still flowing.

May 24, *Hamburg*.—A fall of so-called "blood rain" occurred in Hamburg and district. It was found that the phenomenon was due to the presence of numerous insects (*Carabus coccinella*), and it is suggested that they were driven with volcanic dust from Martinique.

May 25, *Fort de France*.—Mont Pelée is fairly quiet, although there have been eruptions of ashes which covered the extreme north of the island. The new crater is active.

May 25, *Geneva*.—Grey snow fell in the canton of Lucerne. The heaviest fall was at Langenthal. When it melted, a substance resembling ashes covered the grass.

May 26, *Vienna*.—At noon to-day the seismological apparatus at the observatory of Laibach, Carniola, recorded strong earthquake shocks within a distance of 473 miles.

May 27, *Fort de France*.—A fresh and very violent eruption has taken place. The crater has projected a heavy rain of ashes and gravel over the north of the island. At the same time thick clouds charged with electricity floated in the air.

The fears that existed amongst those who escaped the disasters which took place between May 7 and 10 that volcanic wrath was not expended have been fully realised. Devastation has succeeded devastation, fertile slopes have been doubly buried, new craters have been opened and molten rock yet flows. On Thursday, May 8, at about 11.50 a.m. in our time, Mont Pelée did its worst. La Soufrière commenced earlier, and fought the heavens and all within its reach for several days. Next came a period of comparative tranquillity, Pelée for twelve days and La Soufrière for seven, but the hopes that this created were destined to be rudely shattered by terrific explosions and fresh bombardments. Surely we may now expect, although spasmodic ejections of vapours, ash and lava will yet occur, that these Titans must, by a process of natural exhaustion, sink back to their original quiescent state. But what about the nerve-shaken survivors who yet feel tremblings of the ground and yet breathe fumes wafted downwards from the peaks which dominate their homes?

During the preliminaries which ushered in the great explosion, when the air was filled with noxious exhalations and soft white ash carpeted streets as if the doomed who remained within their houses were to pass away without hearing the hurrying footsteps of those who rushed aimlessly along in their endeavours to escape, *pater nosters* were heard from thousands on their knees. Both men and women lost their reason, a mental paralysis was far-reaching, while the sincerest prayers that were ever offered were accompanied by hysteria.

Many sought refuge in the churches, where sacraments were exposed and services were held. Here, with eyes beyond tears, multitudes with terror graven on their faces confessed and prayed, listened to the exhortations of their pastors and the thunderings of the mountain, awaiting their end. During this reign of terror, which lasted for five long days and nights, no doubt many succumbed.

Then came the final crash, and with a blast of poisonous, suffocating gas, a whirlwind of flame, and beneath a rain of hot ash and blocks of rock, a fair township and its surrounding hamlets which had nestled on Pelée's western strand were seen no more. Only one, we are told, escaped the deadly gas and fire. He was a negro charged with murder, shut up in a subterranean prison. The destruction was even more complete and terrible than that which was accomplished by brimstone and fire in the days of Lot.

When the more violent thunderings ceased, let us consider what next happened amongst the survivors around the desert of desolation. The majority rose from their knees, to be terrified by every puff of steam they saw and to rush from their houses at the slightest tremor of the ground. For years to come, not only will the eruptions in Martinique and St. Vincent form a subject of conversation, but the month of May and the year 1902 will, like the twenty-seventh year of Uzziah, when a mountain near Jerusalem was moved 500 paces and the temple rent in twain, mark a period from which to date events. No doubt survivors are yet pouring into each other's ears fresh tales of horror, whilst grumblings in the distant hills result in delirium and prayers. Many will no doubt sing hymns and devote themselves to religious exercise, and perform acts of penance. Noorthouck, in his "History of London," writing about the effects of earthquakes and referring to that which occurred in the West Indies in 1691, tells us that "such intermittent fits of reformation excited by fear resemble death-bed repentances too much to merit any encomium."

Although Noorthouck's view is sustained by the action of those who had courage to back cupidity by returning to the still smoking débris which represented St. Pierre and rob from corpses, yet those who write the history of this disaster will no doubt find that the shock which the nervous system of survivors sustained has had some lasting effect. By this time, no doubt, not only in the West Indies, but throughout the world, these eruptions have afforded materials for many sermons and moral discourses, and for some time to come a cloud of smoke from the throats of Pelée or the Soufrière will claim a *misericordia* in response.

After the disaster which overtook Jamaica in 1691, we understand that a sentence was interpolated in the Litany as used in that island, whilst the special prayers which have been formulated in consequence of volcanic disturbances are numerous throughout the world. In the history of nations we read that these outbursts have resulted in officially ordered prayers, gifts to temples, special services, the repeal of taxes considered to be unjust, and in many other directions have had a more or less permanent effect upon the social, religious and civil lives of many people.

Those who dwell in countries like our own, where displays of volcanic activity are unknown, possibly think themselves beyond the pale of the emotional influences which they exert. When, however, they call to mind the fact that the vulgar of many nations, to use the words of Buffon, have regarded volcanoes as the mouths of hell, their bellowings to be the cries of the damned and the eruptions the effects of the fury and despair of the wretched prisoners, and add to this the fact that throughout all history equally strange ideas have immediately followed on the heels of unusual displays of volcanic and seismic activity, it is difficult to suppose that any nation can exist that has not suffered or been benefited by these mental aberrations. In Japan we have the myth of the buried cat-fish which shakes the empire, and the effect of this poetical idea is met with in the pictures and art of that empire; whilst parallel stories with their parallel effects are found in many other countries. The strange thing is that these emotional creations seem to spread far beyond the limits of the ashes and the tremblings which produced them, to flourish where the imaginative faculty is the strongest. Although we are without volcanoes, we have only to recall names like Pluto, Vulcan and Poseidon and the line in the Decalogue which tells we are not to make any likeness of that which is in the earth beneath to realise that volcanic activities have had

a marked effect upon our religion, our literature, our pictorial and our glyptic art.

Those who visit the West Indies with the object of extending our knowledge of vulcanology will no doubt collect information bearing on these far-reaching effects, and it is not unlikely that it will be found that the eruptions in the Antilles have done more to stimulate the imaginations of Europeans than those of the negroes who witnessed all that happened.

Another neglected chapter in hypogenic geology to which attention may be directed relates to the effects of volcanic activity on epidemic diseases, a subject which has attracted the attention of many investigators. American and Italian statistics, Dr. Bardswell says,

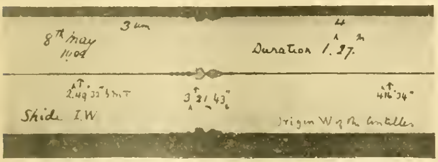

FIG. 1.

show that there is "an increased death-rate from malaria, enteric, &c., with a lessened death-rate from phthisis in areas associated with volcanic activity as compared with non-volcanic regions"—a statement, however, not beyond criticism.

No doubt types of neurosis like nausea, disordered sensation, nervous apprehension, insanity, paralysis of the limbs and other kindred troubles will have a sporadic existence, but it does not seem likely that these will be so marked amongst the negroes as amongst the Europeans.

The destruction of water-pipes or the contamination of water supplies by sewage might result in diseases like cholera and typhoid. Although cases of bronchitis have resulted from the inhalation of volcanic gases, diseases arising from these causes are extremely rare.

An ingenious theory, showing the possibility of a relationship between volcanic action and the production of epidemic diseases, is one advocated by Dr. W. G. A. Robertson. He does not assume that poisonous products issue from volcanic vents to render the atmosphere poisonous, or even that these products appreciably affect its constitution. What, however, he does assume is that these gases and vapours may be dilated to an immense extent to produce an atmosphere suitable to the vital activity of unicellular organisms. According to this view, microparasites, which are always present somewhere or other, may be stirred into activity in regions far removed from volcanic centres, to result in diseases which may affect, not only animals, but also plants.

The causes of death in St. Pierre were no doubt manifold. First there was the blast of irritating gas and dust which caused suffocation. In all probability this gas was in the main that of hydrochloric acid derived from the sodium chloride of the sea-water, the infiltration of which is the main cause of all volcanic activity. This gas has been pouring out of Pelée and La Soufrière in the columns of steam during all stages of their eruptions and by this time, no doubt, it exists as a belt round our world, many of the inhabitants of which are breathing exhalations which had their origin in the West Indies.

Many were killed, particularly at La Soufrière, by a rain of hot ashes or by lightning, which played in the darkness of the ashy cloud like fiery serpents.

On May 8, when Pelée burst an opening on its flanks, a whirlwind of fire or a sheet of flame, followed by red-hot ashes, stones and boiling water, swept over St. Pierre and its harbour to seer and scald and fire all that it passed. We have here a phenomenon deserving close attention. If this flame really existed, what was its origin? Mr. F. J. M. Page gave the writer the suggestion that it was the ignition of a "water gas" produced when the water forming the lake in the crater of Mont Pelée was suddenly admitted into the fiery furnace of its interior. The action would be similar to that which takes place when a teaspoonful of water is thrown upon a hot fire; dissociation would take place, an explosion would occur, and the resultant gases would be ignited as a flash. That the inhabitants of a city should be overwhelmed by a wall of fire created by the cool waters of the lake in which they bathed seems incredible, but still, this is at present the only explanation we have for this unparalleled occurrence.

About premonitory signs a correspondent of the *New York Herald* tells us that dumb animals were wiser than man, live stock were uneasy and almost uncontrollable. Cattle lowed in the night, dogs howled, and when driven out showed symptoms of fear. Wild animals disappeared from Mont Pelée. Even snakes crawled away. Birds ceased singing and left the mountain, and a great fear seemed to be upon the island.

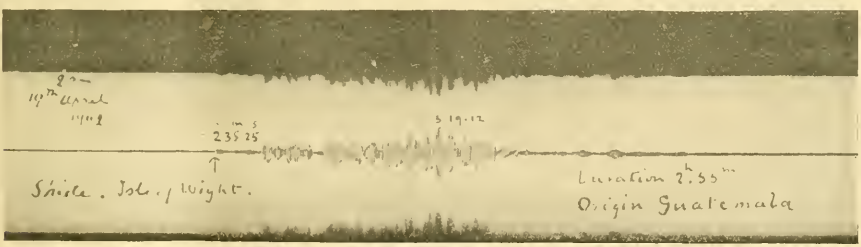

FIG. 2.

Signs like these, which usually are only recognised after a catastrophe has taken place, are by no means peculiar to the Antilles. The late Prof. S. Sekiya, of Tokio, kept pheasants to study their behaviour before an earthquake, and I have had many opportunities of confirming his observations, which show that these birds by their screaming feel the preliminary tremors of an earthquake, to which movements human beings are insensible. This, then, being the case, it does not seem at all unlikely that the creatures living on the slopes of Mont Pelée heard sounds and felt vibrations the occurrence of which was not noticeable by man. Although

Cicero, in the "De Divinatione," says that "God has not predicted so much as the divine intelligence of man" and omitted reference to the intelligence of the lower animals, it seems probable that in certain directions the instinct of brutes is not to be overlooked.

The small earthquakes which frequently precede a volcanic eruption are usually referred to as abortive attempts made by internal forces to establish an opening. But should all such earth shakings be regarded in this manner? It seems likely that some of them may be simply intermittent yieldings in the general process of rock folding, which, when it has sufficiently relaxed its hold upon the imprisoned vapours, allows the same to burst forth as an eruption. Whether before the eruption there were unusual escapes of gas from subterranean sources, whether there had been changes in colour, taste, level or temperature of the water in wells and springs, we have not yet been told.

Neither have we been told of any prophet who boldly came forth and announced the impending danger; but what we do know is that whilst the Governors of the Windward and Leeward Islands are yet striving to allay the fears of terrified inhabitants, thoughtless Cassandras are predicting tornados, new eruptions, and even the sinking of the islands. As we have said before, tornados always occur in these islands between July and October, and volcanic displays usually sink back into quiescence in an intermittent manner. To call attention to what is inevitable in terms suggesting that even greater catastrophes than have yet been experienced are to be expected, may make sensational paragraphs and cheapen property. It can, however, only excite alarm, create panic, trouble the civil administration and accelerate the depopulation of the islands, and therefore prognostications of this character should at least be discouraged. What grounds there are for supposing that the Antilles may sink beneath the ocean is a mystery. Cinder heaps which have risen above the ocean as volcanic islands have by the action of the waves been reduced to shoals, but with the Antilles we are dealing with a fold in the crust of our earth which, if the water was removed from its flanks, would stand up like a chain of mountains 18,000 feet in height. Parallel with this is the fold of the Cordilleras, with its peaks 12,000 feet in height, bounded by an ocean more than 14,000 feet in depth.

It seems that it was an adjustment in this latter fold which took place on April 19, when several towns were ruined and more than 1000 people lost their lives, which led to adjustments announced by earthquakes in the parallel Antillean fold. Pelée then smoked, indicating that pressure had been relieved. This relief suggests elevation, and that elevation rather than subsidence is the direction of movement in these islands is testified by a variety of geological evidence.

From this it would seem that, instead of issuing an alarming prediction that the West Indies are to disappear from view, the recent eruptions suggest that they have risen to a greater height, whilst the water on their Caribbean side may have deepened. Two wrinkles on the face of the world have probably gained in height, whilst the depth of the bounding furrows on their western flanks has probably been increased. As indications of these changes, newspapers state that Richmond in St. Vincent has risen, whilst a French cable ship has found at a certain spot an increase in the depth of water of nearly 500 fathoms.

The public are evidently anxious that volcanic eruptions and seismic disturbances should be predicted, but as districts where these activities prevail are not transparent and we cannot see what is happening beneath our feet, neither are we able to measure the pressures and strains which may be increasing in such regions, the time when a ball rising on a mast will announce impending subterranean disturbances seems very distant. Still, there are directions in which investigations bearing on this point may be pursued. One of these would be to determine whether before a volcanic outburst or after the same there were any unusual changes in level in operation. Lyell remarks that if we reflect upon the dates of the principal oscillations noted near the Bay of Naples, there appears to be a connection between the movements of upheaval and a local development of volcanic heat, whilst periods of depression are concurrent with periods of volcanic quiescence. The part that the horizontal pendulum would play in such an investigation is obvious.

A second-line of research would be to determine whether the movements of magnetic needles placed in the vicinity of a volcano show any relationship to its eruptions. We know that many lavas are highly magnetic, and it is not unlikely that physical and chemical changes, together with mechanical displacements of such materials, would result in changes in magnetic elements in their vicinity; and that remarkable coincidences between such changes and volcanic eruptions have taken place has been indicated by Captain E. W. Creak, F.R.S.

There may be other lines of research which would throw light upon subterranean operations, but these are two which might be pursued without great difficulty.

On the Sequence of Events.

From the enormous displacements of ground which have frequently accompanied world-shaking earthquakes, and from the fact that their origins can be traced to districts where we have evidence of secular movements which may be yet in progress, it is not unreasonable to suppose that such earthquakes are announcements that strains have suddenly been relieved in certain orogenic foldings. This relief may be compared to the movement of a key which fires many mines. Not only might volcanic vents beneath which there was excessive pressure burst into activity along the fold, but similar displays might be expected in neighbouring folds. In support of these views attention may be called to the fact that the mountain-making epochs in geological history were periods of intense volcanic activity. From the middle to the end of the eighteenth century, earthquakes and volcanic eruptions were frequent throughout the world. The history of the large earthquakes of Japan shows an approximate coincidence in time between these phenomena and volcanic eruptions, and similar coincidences can be adduced from the registers of other countries.

Evidences of this description suggest a relationship between pronounced seismic efforts in or near a volcanic region and volcanic activity, and when we know the sequence of events which have recently occurred in the West Indies and Central America, our knowledge of the relationship between earthquakes and other subterranean phenomena may be extended. The seismograms reproduced in Figs. 1 and 2 are of interest in this connection.

On April 19 at about half-past two in our time, the Cordilleras of Central America were suddenly relieved of seismic strain, villages and towns were shattered, earthquake waves passed all over our world and all through the same, whilst in the epifocal area we learn that at one town alone 1100 people lost their lives. Whether this widespread disturbance was quickly followed by adjustments in the neighbouring Antillean ridge we are not certain. All that can be gathered from newspapers is to the effect that *about* the end of April many small earthquakes took place and Mont Pelée smoked and rumbled. On May 3 this mountain was in eruption and ashes fell upon St. Pierre. Two days later it ejected a stream of mud and commenced its work of serious destruction. The sea receded 300 feet, and the Puerto Plata and the Dominica-Martinique cables were interrupted. On this

day La Soufrière, ninety miles to the south, gave evidences that it was disturbed, but it was not until 2 p.m. on May 6 that it can be said to have erupted. At 7 a.m. on May 7 the eruption was violent. At noon three craters opened, lava flowed, ashes were driven to a height of eight miles, to fall upon Kingstown, twelve miles distant, whilst the schooner *Ocean Traveller* had to fly to escape destruction from the showers of lapilli. A violent explosion took place at 1.30 p.m., whilst at 3 p.m. the detonations were terrific. One hour later a dust cloud, which apparently had travelled in the teeth of the trades, reached Barbados. Dust or extremely fine ash was falling at or before 5.30, and in three days, when the eruption in St. Vincent moderated, a thin layer of this covered Barbados. The weight of this dust layer, which has already been analysed and is expected to improve the texture of the soil, is estimated at two million tons. This is what La Soufrière, assisted by an upper current of air, effected at a distance of 100 miles eastwards from its crater. It may here be noticed that this mountain commenced its violent outbursts, which extended over three days, before the explosion of Mont Pelée, which happened at 11.50 a.m. on May 8, although Mont Pelée was in eruption some days before La Soufrière.

The *Dies Irae* for St. Vincent was May 7, whilst for Martinique it was on May 8. Other events of considerable significance which happened on May 7, but about which we have as yet but little information, were, first, the St. Lucia-Martinique, the St. Lucia-St. Vincent, the St. Lucia-Grenada and the Guadeloupe-Martinique cables were interrupted; second, at 10 p.m. a very strong earthquake shook St. Vincent; and lastly, in St. Vincent time in the Isle of Wight a seismograph commenced to indicate at 10h. 45m. p.m., the maximum motion being attained at 11.16 p.m. The character of the seismogram is that of a disturbance which originated at a distance from the Isle of Wight of between 60° and 70°. From this it is inferred that the time at which this disturbance originated was about 10.33 p.m.

Now St. Vincent is 60° from Great Britain, but whether the earthquake which took place in that island is identical with that recorded in Britain and represents a suboceanic convulsion which interrupted the cables on that date can only be definitely settled by those who know the hours at which these cables ceased to work.

The suboceanic disturbance which at 6.32 a.m. on December 29, 1897, interrupted the cables off Hayti gave in England a seismogram which was comparatively large. In this case, although the seismogram is small if we for the present assume the disturbance it represents to have originated off St. Vincent, it indicates that the sudden adjustments in the earth's crust accompanying the eruption of La Soufrière were more violent than those which took place around Mont Pelée, from which earthquakes of any magni ude do not seem to have originated. The considerations attending the laying of cables are no doubt numerous, but from the fact that those which have been mentioned for the most part pass along the western side of the Antilles, it cannot be said that they occupy the best position o avoid the effects of submarine convulsions. A comparison of the registers of the interruptions these cables have experienced with those of earthquakes which may have been recorded at many very distant stations would throw great light upon the geological activities in progress beneath the Caribbean Sea.

To turn back to Mont Pelée and La Soufrière, we see that after their paroxysmal efforts, when 2000 lives had been lost in St. Vincent and 40,000 in Martinique, the eruptions at these mountains moderated, but this was only for a time. On May 17 another great eruption took place at La Soufrière, whilst on the 20th Mont Pelée destroyed everything that had remained standing at St. Pierre, and, as if filled with a desire to destroy more life, showered stones and ashes on Fort de France, thirteen miles distant. The northern ends of two islands have now been destroyed and the eruptions continue, whilst in St. Lucia, which lies at a distance of about twenty miles from each of these scenes of destruction and exactly between them, the boiling sulphur springs and volcanoes remain in their normal conditions.

With the great eruptions of Pelée on May 3, 8, 19 and 20 there appear to have been disturbances of sea level, the water either rising or receding. With that of La Soufrière on the 17th, we read that at Château Belair every few hours there were continuous convulsions of the ground, at Kingstown and Georgetown there were sixty shocks in four hours, whilst the village of Wallibou partly sank and that of Richmond rose. All these phenomena, taken in conjunction with the interruption of cables, indicate that the more violent displays of activity were accompanied by adjustments in the neighbouring strata, and it is more likely that such adjustments were the cause rather than the result of the marked phases of activity.

About unusual phenomena which occurred at a distance we have as yet but little information.

On May 11 a geyser or boiling lake in Dominica, some 300 feet in length and 200 feet in breadth, disappeared. The next day some boiling springs at Bath, in Jamaica, became extremely hot. On May 13, and for several days previously, Pico de Colima, a volcano 12,700 feet high, in Mexico, created alarm by belching forth puffs of smoke, whilst at St. Thomas at 4.30 p.m. a slight earthquake was felt. On May 18 an earthquake was felt throughout California. Up to noon on Sunday, May 25, with the exception of what has here been noted, the instruments in the Isle of Wight have been at rest.

J. MILNE.

Volcanic Ash at Barbados.

Volcanic ash fell very thickly at Barbados in the afternoon of May 7, in consequence of the eruption of the Soufrière on St. Vincent, and caused almost total darkness in the afternoon. On the morning of May 8, we learn from the *Barbados Advocate*, kindly sent to us by Sir William Thiselton-Dyer, the streets were found to be covered with this grey dust, and it was estimated that about twenty-two tons per acre fell in twelve hours. The ash lay so thick in the streets that traffic was interfered with, and great difficulty was experienced in clearing it from houses and approaches.

There was a fairly strong east wind prevailing during the whole period, and ordinarily speaking, St. Vincent being to the west of Barbados, it would have been considered impossible that the dust could have travelled in this direction nearly a hundred miles against the wind. But whilst the prevailing direction of the wind was from the east, the upper currents of air travelled from the west, and the phenomenon observed in the eruption of 1812 was repeated in the present. The dust was hurled from the volcano into the upper strata of air and borne eastward against the direction of the surface currents.

According to the official statement in the *Agricultural News*, the quantity of ash that fell varied from three-eighths to half an inch in depth, covering everything with a grey mantle of impalpable dust. By actual measurement it was ascertained that the weight of ash was at the rate of 17·58 tons per acre, probably nearly two million tons being deposited over the whole of Barbados. Prof. d'Albuquerque's preliminary chemical examination led to the conclusion, which was contrary to expectation, that the ash was of no fertilising value, but that it may tend to improve the texture of the surface layers of heavy clay lands. Dr. Longfield Smith's preliminary mineralogical examination disclosed volcanic minerals and volcanic glass, the minerals predominating, and consisting chiefly of silicates of iron and magnesia, also a considerable proportion of quartz and some potash felspar. Under

the microscope the samples of the dust which fell in 1812 and 1902 differed greatly, the 1812 dust being much finer and containing very few mineral crystals, being chiefly composed of fragments of dark brown volcanic glass. During the recent fall it was noticed that the ash at first was rather coarse and of a brownish colour, then it became slightly redder, while the final deposits consisted of a whitish-grey impalpable powder.

From a meteorological standpoint the conveyance of the dust from St. Vincent to Barbados is a subject of great interest, as bearing upon the question of the upper currents. At sea level the trade wind blows almost directly, and freshly, from Barbados to St. Vincent, east to west. The Soufrière became active early in the afternoon of Wednesday, May 7; the dust cloud must have been shot up to an elevation of some miles, where it was caught by a west to east counter current of great velocity, for within two hours, 3.15 p.m., dust was observed to be descending in Barbados, gradually increasing in volume and becoming heavy soon after sundown, the consequent darkness being intense. There was brilliant lightning and violent crashing thunder. It would appear that on this day the upper current had an east-going velocity of more than fifty miles an hour.

It is worthy of mention that at 1.30 p.m. on May 7 there occurred a sudden outburst from one of the oil borings, 900 feet deep, at Turner's Hall, Barbados, dust being thrown up to the height of more than 100 feet into the air. At 3.45 p.m. there was an unusually high tide at Bridgetown, the highest within memory.

Seismographic Records in France.[1]

I received, on May 6, a telegram from M. Kilian, professor of geology at the University of Grenoble, announcing that the Kilian-Paulin seismograph had registered in the morning at 3h. 4m. 49s. Paris time a seismic shock from a north-east direction. The evening papers and those of the next day announced that this shock had been felt again in the north-west of France and along the south Mediterranean coast of Spain. It is in the district of Murthia that the most violent effects were notified.

Another more precise observation as regards time and direction of the shocks has been recorded at Floirac near Bordeaux, north-west direction, time 3h 5m. 30s.; the passage of the vibrations therefore made themselves felt at Floirac forty-one seconds after those of Grenoble. In supposing them to have a speed of 3 km. a second, the epicentrum must be 123 km. further from Floirac than from Grenoble and also to the south-east of Floirac, to the south-west of Grenoble. These theoretical and hypothetical considerations would place it in the Mediterranean, to the east of Murthia, to the south of Minorca. Wherever it is, it seems to me that the earthquake of May 6 affected the subsidence in a Mediterranean oval, which has cut the south coast of Spain, by marking it with volcanic eruptions (Olot, Columbret, Cartagena, Cap de Gâte). It is interesting to remark that it is equally the result of a subsidence in a Mediterranean oval, that of the Lesser Antilles, that two days after, May 8, there was the terrible catastrophe of Saint-Pierre.

NOTES.

At the next meeting of the British Association, to be held at Belfast, commencing on September 8, it has been decided to include in Section A a subsection for seismology. The organising committee of this subsection invite cooperation of seismologists, who, it is hoped, if they are not able to attend will be able to send communications for discussion.

A Reuter telegram from Upsala says that a Swedish expedition for taking meridian measurements will leave Tromsö for Spitsbergen on July 26. It will be under the leadership of Dr. P. Rubin and will include, as astronomer, Dr. von Zeipel, and, as cartographer, Lieutenant Duner. The expedition will have as a centre the seven islands to the north of Spitsbergen, and will return to Tromsö on September 10.

Mr. J. S. Budgett, Balfour student of the University of Cambridge, left England last week for Uganda, *viâ* Mombasa, on a mission from the Zoological Society of London. He will proceed to the south-east corner of the protectorate, and take up a station on the Semliki River, where he will collect mammals and birds, study the fishes, and endeavour to investigate the habits of the okapi in the forest of Mboga. Mr. Budgett, who has already paid two visits to the Gambia, is a practised collector of fishes and an experienced African traveller.

At the anniversary meeting of the Royal Agricultural Society, held last week, the Prince of Wales was elected president of the Society for the year following the Carlisle meeting this summer.

The *British Medical Journal* announces that a scientific commission, consisting of Dr. G. C. Low, Dr. C. Christy and Dr. Castelani has been sent to Uganda by the Royal Society for the purpose of investigating sleeping sickness. To Dr. Low and Dr. Christy is entrusted the parasitological part of the investigation, while Dr. Castelani is the bacteriologist of the expedition.

We learn from the *Victorian Naturalist* that after an absence of rather more than twelve months, the greater part of which was spent among the aboriginals of the northern interior of Australia, Prof. Baldwin Spencer, F.R.S., and Mr. F. J. Gillen returned to Melbourne on March 17. They were in excellent health, and were welcomed home by a number of gentlemen prominent in literary and scientific circles. The explorers have brought back a considerable amount of material, including phonograph and kinematograph records, on which to base an extensive work on the myths, customs, &c., of the various tribes studied.

The *Times* states that Mr. W. Bruce, who is to lead the Scottish Antarctic expedition, has received intimation, dated January 4, from Prof. von Drygalski, leader of the German South Polar expedition, announcing the arrival of the *Gauss* at Kerguelen. The expedition will, therefore, have made the ice at about the same time as the Swedish and British ships. Von Drygalski has penetrated the Antarctic region at the point of the still hypothetical termination island in order to discover the western side of Victoria land and clear up its possible connection with Kemp and Enderby lands. By taking this route he believes he may be ultimately able to sweep westwards by a high southern latitude into the South Atlantic and emerge by way of South Georgia.

A correspondent directs our attention to the announcement that a very fine example of the blue Puya is in flower in the Mexican portion of the temperate house at Kew Gardens, where it is now bearing two stout spikes, three feet high, of beautiful peacock-blue flowers. The plant is a very remarkable one and has rarely flowered in this country, though Messrs. J. Veitch had one in flower in 1868 (*Botanical Magazine*, t. 5732).

The International Commission for Scientific Ballooning met in Berlin last week in the Sitzungssaal of the Reichstag. We learn from the *Daily Graphic* that Prince Frederick Henry presided in the name of the Kaiser. The War Offices of all the great European Powers except France were represented at the conference. The object of the commission is to combine the study of meteorology with aëronautics, and to induce the various Powers to agree upon some common course of action with regard to the study of aëronautic questions. A paper was read by Mr. Patrick Alexander on the steering by Hertzian waves of flying machines carrying instruments for registering the temperature and moisture of the atmosphere at different altitudes. Mr. Alexander claims that his machines can be sent a distance of fifty miles and steered back to the

[1] Translation of a note by M. Michel Lévy in the *Comptes rendus* of the Paris Academy of Sciences, May 12.

starting point. The foreign deputies, who were the guests of the aëronautical battalion of the German Army, were shown over the headquarters of the battalion, which has the largest balloon house in the world.

THE anniversary meeting of the Royal Geographical Society was held on Monday, and the medals and awards already announced (vol. lxv., p. 471) were distributed. In his opening address, the president referred at some length to the Antarctic expedition, and remarked that they could not hope to receive any news of the *Discovery* until the spring of next year. The question of wintering was left to Captain Scott's discretion, and he was instructed to use his utmost endeavour to explore the region within reach of his winter quarters by sledge travelling in the spring. He intended to endeavour to reach and force through the ice pack on the 175th meridian, and on reaching the open water to make for Cape Adare. The relief ship would have no difficulty in finding the *Discovery* and supplying her with the stores and provisions of which she would be in need if the winter quarters were in Wood Bay or on any part of the coast between that position and Cape Crozier. About 20,000*l.* had been subscribed for the relief expedition, but at least 22,000*l.* would be needed. Turning to the opposite Polar area, the president remarked that the Arctic regions were the scene of the labours of four expeditions. The *Windward* would shortly proceed to Smith Sound to bring back the Peary expedition. Captain Sverdrup in the *Fram* had now been absent three winters, and his exact position was unknown. There were also Mr. Baldwin's expedition with the avowed object of reaching the North Pole by the Franz Josef Land route, and Baron Toll's expedition in the islands to the north of the new Siberian Islands.

THE Nature-Study Exhibition, to be opened at the Gardens of the Royal Botanic Society in Regent's Park on July 23, promises to be of a very interesting and instructive character. The exhibits will be arranged in five groups, the scope of which may be roughly defined as follows:—(1) General information, such as reports and other publications, object-lessons and notes on school gardens, natural history rambles, &c.; (2) pictorial illustrations, including pictures and photographs of work and equipment in school and out; (3) organisation, with schemes of instruction and time-tables; (4) apparatus, including models, specimens, maps and collections of natural objects; (5) work done by pupils, such as notes of observations, nesting-boxes, breeding-cages, &c. The intention is to bring together, so far as possible, the results of nature-study in schools and colleges of all grades, so that teachers and pupils may be given the opportunity of seeing what others are doing, and so obtain inspiration for the further development of their work. University colleges, natural history societies and local museums might usefully affect the trend of nature-study by showing typical collections, or materials and apparatus suitable for study in various branches of natural history in schools. A report will be published, and the following have kindly consented to act as judges:—Mr. A. D. Hall, principal South-Eastern Agricultural College, Wye, Prof. C. Lloyd Morgan, F.R.S., Prof. L. C. Miall, F.R.S., Prof. J. Arthur Thompson and Prof. R. Wallace. The scheme has so far extended beyond the scope originally contemplated that further donations are invited and would be gratefully received by the hon. treasurer, Mr. C. S. Roundell, 7 Sussex Square, Brighton. All particulars may be obtained from the hon. secretary, Mr. J. C. Medd, Stratton, Cirencester.

THE *Times* announces the death of Dr. Henry Morton, president of the Stevens Institute of Technology. Dr. Morton was born in New York, December 11, 1836, and graduated from the University of Pennsylvania in 1857. The bent of his studies was then fixed by the fact that he took a post-graduate course in chemistry. He afterwards became secretary of the Franklin Institute of Philadelphia, where he delivered many lectures which attracted much attention. In 1868 he was the chief of an expedition organised to observe and make photographic records of a very notable total eclipse of the sun. In 1870, the Stevens Institute of Technology was organised and its work begun at Hoboken in New Jersey. This was done under the will of Edwin A. Stevens, who had designated Dr. Morton as the president of an institute to be devoted entirely to the higher instruction in technological subjects. Dr. Morton was one of the most proficient of the engineering experts known to America. He lavished his large income upon the institute with great freedom. In 1880 he made his first gift, which took the form of a new workshop fitted up with steam engines and tools. Two years later he gave money for the purchase of electrical apparatus. In 1888 he gave 10,000 dollars for the endowment of a chair of engineering practice, to which, in 1892, he added 20,000 dollars more. For many years he had contributed the whole of his salary as professor of applied electricity to electrical experiments. In all, his gifts to the institute have amounted to about 145,000 dollars. A few years ago he interested Mr. Andrew Carnegie in the work, with the result that Mr. Carnegie contributed a laboratory and endowed it in addition with 100,000 dollars. Dr. Morton was for several years a member of the United States Lighthouse Board and had been a member of the National Academy of Sciences for nearly thirty years.

MR. JOHN BELLOWS, who died on May 5, aged seventy-one, was a well-known member of the Society of Friends, and a printer at Gloucester. He was an active member of the Cotteswold Naturalists' Field Club, and had communicated to its *Proceedings* several papers on local archæology. In one paper he dealt elaborately with the history of the "Speech House" in the Forest of Dean, and endeavoured to show that in the Court still held in that house we have the last vestige of the grand system of the Druids in Britain.

IN connection with the Belgian Royal Academy, a number of prizes are offered for this and next year of which particulars are given in No. 3 of the *Bulletin de la Classe des Sciences*. In mathematical and physical sciences the subjects announced for 1902 relate to critical phenomena, viscosity of liquids, the algebraic and geometric study of n-linear forms where $n > 3$, and the thermal conductivity of liquids and solutions, the prize in each case being 600 francs, also prizes of 800 francs for researches on the action of alcohols on compound ethers and on the unipolar induction of Weber. In natural science, prizes of 600 francs are offered for a study of the beds of Comblain au Pont and their geological position, the modifications produced in minerals by pressure, the development of the Platoda, the effects of osmotic pressure on the phenomena of animal life, and the Devonian flora of Belgium. For researches on the influence of external factors on karyokinesis and vegetable cell division a prize of 800 francs is offered, and for new investigations on the formation of albuminoids in plants a prize of 1000 francs. In every case the essays, written in French or Flemish, must be sent in by August 1. For 1903 the subjects propounded in mathematical and physical sciences are the combinations of the four halogens among themselves, the form of the principal terms introduced by the earth's elasticity into the equations for the nutation in obliquity and longitude, contributions to the study of mixed forms containing any number of series of variables with applications to the geometry of any space, and the determination in altitude and azimuth of the principal terms in the periodic deviations of the vertical on the hypothesis of the non-coincidence of the centres of mass of the earth's crust and its nucleus. In natural science the subjects are the physiological function of

albuminoids in the nutrition of animals or plants, the organisation and development of a Phoronis, and the relations between this genus and Rhabdopleura and Cephalodiscus and the group of Enteropneustes, a description of the elements and their sulphides and binary compounds occurring in Belgian soils, new researches on the different strata included between the "Bruxellian" and "Tongrian" in Brabant, and a determination of the geological age of certain deposits of sand, plastic clay and quartz pebbles in the Oligocene formations the positions of which are indicated by reference to the geological maps. The values of these prizes range from 600 to 1000 francs.

IN addition to the above prizes, a prize of 1400 francs associated with the name of Charles Lemaire is offered for questions relating to public works. A prize, named the Édouard Mailly prize, of 1000 francs is offered to the Belgian or naturalised subject who makes the greatest advance in promoting the study of astronomy in Belgium, a Louis Melsens prize is offered for work on chemistry or applied physics and a Charles Lagrange prize for a mathematical or experimental investigation relating to our *mathematical* knowledge of the earth, the word mathematical in this sense excluding purely statistical measurements unless associated with the investigation of some new law. Finally, a prize founded by Baron Selys Longchamps is offered for the best original work dealing with the whole or part of the Belgian fauna, not necessarily the recent fauna.

HAVING regard to the wide reputation which the Malays have earned for themselves as a maritime people in Eastern seas, it is at first sight not a little remarkable that, so far as the Malay Peninsula is concerned, they have developed no really able type of sea-going boat. Three main factors have been at work influencing the development of boats, and tending to produce the characteristic shallow draft, lack of beam, and a consequent want of stability and weather lines. (1) The rivers are protected by very shallow bars of sand or mud, which make it impossible for a deep-bodied boat to obtain shelter within them. (2) The variable character of the light breezes prevailing in the Straits of Malacca. (3) The great strength of the tides. The lot of the sailing vessel is thus precarious; racing tides and baffling winds and calms make progress very slow. Hence propulsion by oars or paddles was the first necessity of the old-time Malay seaman in the Straits; sails were merely an occasional convenience. The Malay boat, however large and with its quantity of top-hamper, always remains essentially a canoe. Those who are interested in the subject of transport by water will find an important paper on boats and boat-building in the Malay Peninsula, by Mr. H. Warington Smyth, in the *Journal* of the Society of Arts, vol. l. p. 570.

IN *Symons's Meteorological Magazine* for May, attention is drawn to the use of the rainfall tables published each month. The British rainfall organisation established by the late Mr. Symons has been very successful in obtaining the voluntary assistance of some thousands of observers, and it is well known that the results are very carefully collated and published in an annual volume, "British Rainfall." It is, perhaps, not so generally known that in the monthly magazine the rainfall values for some 156 stations are regularly published, so as to give prompt and accurate information as to the state of the British Islands as regards rainfall in the previous month. For forty-five of the stations the departures from the averages for the ten years 1890–99 and also the number of rainy days are shown. In the current issue a table is given showing the aggregate rainfall of the first four months of this year and the averages of the same period, for ten years, at more than fifty stations distributed as uniformly as possible over the country. A glance at this table shows that the south-eastern portion of England has been very dry; within a radius of fifty miles from London the fall has only exceeded two-thirds of the average at London itself. With regard to large districts, the actual state is perhaps more readily seen from the *Weekly Weather Report* of the Meteorological Office, which shows that for the four months in question the rainfall has only exceeded the average in the north of Scotland and the north of Ireland; in the east of Scotland, and the east and south of England, the deficiency exceeded two inches, while in the south-west of England it exceeded three and a half inches.

THE Meteorological Office pilot chart of the North Atlantic and Mediterranean for June shows that down to the middle of May no reports of ice about the Newfoundland banks had been received, a newspaper report of a berg having been seen in a locality much frequented by shipping not being confirmed. Of interest in connection with the exceptionally prolonged spell of cold weather over the British Isles is the statement that during April there was much Polar ice blocking the north and east coasts of Iceland, the region from which the prevailing winds have recently been drawn. In a note on sandstorms it is suggested that the dust which fell in the south-west of England and South Wales late in January last may have come from a sandstorm which had been observed at Ouargla, in the Sahara, on the 16th of the month, falls of sand being reported on succeeding days about the Canaries, Madeira, Portugal, the north-west of France, and finally on our side of the Channel on the 22nd and 23rd. Curiously enough, on the 17th and 18th, when brisk easterly winds were carrying dust from Africa to the Canaries, a westerly wind, strong to a gale, was driving clouds of sand across the Gulf of Suez and the upper part of the Red Sea. From a total of 3200 observations of the temperature of the North Atlantic during the month of March, it is found that, compared with February, the changes were very irregular, the mean values in several localities, chiefly between 30° and 40° N., showing a decline. A strip of very cold water extended southward from the extremity of the Newfoundland bank down to the forty-first parallel, several records being as low as 32° to 35°. To the south-westward of the British Isles the mean values differed but slightly from the average, while the air over the land showed an excess of 2° or 3°.

THE third and last part of the sale catalogue of the library of the late Prof. A. Milne-Edwards, of which a copy has been sent us, contains the works on invertebrates. The total number of lots catalogued in the three parts is 2881.

ACCORDING to its report for the year 1901, the Rugby School Natural History Society is in an unusually flourishing condition. A large collection of invertebrates has been purchased, and the museum has been added to and improved in other ways. A satisfactory feature is the attention devoted to agricultural science, the attendance at the meetings of that section exceeding all the rest in numbers.

IN the course of an article on animal sense perceptions, in which special attention is directed to nauseous or offensive odours as a means of protection, the editor of *The Zoologist*, in the May issue, warns his readers against regarding animal etiology too much from the human standpoint. Because animals cannot speak, we must not assume that they have no modes of communication; it is by no means certain that the ordinary explanation of "warning colours" is the true one, while the evil smell of the durian fruit does not render it distasteful either to the orang or to man himself. To the same journal Mr. G. Renshaw contributes an interesting article on mammals in captivity.

THE auditory organs of the so-called "waltzing mice" of Japan and China form the subject of a paper by Dr. K. Kishi in part iii. of vol. lxxi. of *Zeitschrift für wissenschaftliche Zoologie.*

Although these remarkable mice are commonly called either Japanese or Chinese, it appears that their real home is China, since they are known in Japan as Nanking mice. In Japan, where there were originally a grey and a white breed, these mice are kept in cages on account of their well-known dancing propensities. After an exhaustive examination of their internal auditory organs, the author comes to the conclusion that the dancing of these mice is not due, as commonly supposed, to disease of the labyrinth, but to the effect of confinement for untold centuries in small cages.

THE German scientific periodical *Die Natur* has been discontinued as a separate publication, and is now combined with the *Naturwissenschaftliche Wochenschrift*, edited by Prof. H. Potonié and Dr. F. Koerber and published by Gustav Fischer, Jena.

MR. F. HOWARD COLLINS has compiled from Admiralty sources a collection of tables showing "the magnetic direction and neap and spring rates for every hour of the tidal streams at forty-eight localities alphabetically arranged between the Nore and Scilly Isles." The latitude, longitude and characteristics of each light are stated, and under them are given particulars as to directions and rates of neap and spring tides. The tables are published by Mr. J. D. Potter at two shillings.

THE simple experiments in "Mensuration, Hydrostatics and Heat" given by Mr. G. H. Wyatt in the little book published under that title as one of Messrs. Rivingtons' Handbooks of Practical Science, should be familiar to every schoolboy. The book has now reached a third edition, and contains a course of practical work which can be done with profit by boys in the lower forms of schools. Not only do exercises of this kind develop delicacy of manipulation and minute attention to details in the pupils, but they are also of decided value in connection with other branches of school work.

THE additions to the Zoological Society's Gardens during the past week include a Chimpanzee (*Anthropopithecus troglodytes*) from the Gold Coast, presented by Captain Daniel A. Donovan; an Illiger's Macaw (*Ara maracana*) from Brazil, presented by the Countess of Malmesbury; a Common Kingfisher (*Alcedo ispida*) British, presented by Mr. J. F. Smith; a Hocheur Monkey (*Cercopithecus nictitans*) from West Africa, deposited; three White-throated Capuchins (*Cebus hypoleucus*) from Central America, a Humboldt's Lagothrix (*Lagothrix humboldti*) from the Upper Amazons, purchased; a Burrhel Wild Sheep (*Ovis burrhel*), a Japanese Deer (*Cervus sika*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JUNE:—

June 2. 15h. 1m. to 15h. 54m. Moon occults 54 Ceti (mag. 5·8).
2. 19h. 0m. Venus in conjunction with moon. Venus 2° 44′ S.
5. 11h. 58m. to 15h. 40m. Transit of Jupiter's Sat. III.
9. Saturn. Outer minor axis of outer ring = 15″·41.
10. 16h. 0m. Uranus in opposition to the sun.
12. 15h. 37m. to 19h. 20m. Transit of Jupiter's Sat. III.
14. 23h. 36m. Moon in conjunction with α Virginis (mag. 1·2).
15. 10h. 15m. to 11h. 31m. Moon occults 86 Virginis (mag. 6·0).
15. Venus. Illuminated portion of disc = 0·711. Mars = 0·989.
18. 9h. 37m. to 10h. 59m. Moon occults ν Scorpii (mag. 4·5).
22. 23h. Saturn in conjunction with moon. Saturn 5° 11′ S.
June 24. Vesta situated 21′ south of Saturn.
24. 17h. Jupiter in conjunction with moon. Jupiter 5° 54′ S.
26. 12h. 25m. Minimum of Algol (β Persei).
29. 9h. 14m. Minimum of Algol (β Persei).

NEW ALGOL VARIABLE.—*Circular* No. 65 from the Harvard College Observatory announces the detection of a new variable on the photographs obtained there. An examination of a plate taken on April 3, 1902, for the possible presence of comet *a* 1902 showed that as compared with a plate of the same region obtained on March 7, 1900, the star + 43°·4101 was abnormally bright. This star is a double, and it is the north preceding component which shows the variability. The position is

$$\left.\begin{array}{l}\text{R.A.} = 21\text{h. } 55\text{m.}\cdot 2\\ \text{Decl.} = +43^\circ\ 52'\end{array}\right\}(1900).$$

More detailed examination showed that the star was generally bright and constant in light, so that it must be of the Algol type. It is not very distant from the remarkable variable SS Cygni, which precedes it 16m. and is 44′ south.

The variable is shown at full brightness (about 8·9 magnitude) on 388 plates taken between 1889 and 1902, and on 19 it is shown as fainter than 9·3 mag. The period appears to be about 31·304 days. On plotting the light curve from the data obtained it appears that the star retains its full brightness for 28 days. About one day before the minimum it commences to diminish, attaining the magnitude 11·5 at 0d. ·43 before minimum. The light then remains constant for more than half a day, with the minimum magnitude 11·6. The time of increase is more uncertain, but apparently is nearly the same as that of decrease. The times of the last minimum, with predicted future ones, are as below:—

	Minima. h.	m.	
1902 April 28	21	33	G.M.T.
May 30	4	51	
June 30	12	8	
July 31	19	26	
Sept. 1	2	44	
Oct. 2	10	2	

COAST FOG SIGNALS.

WHEN lighthouse lights and all other seamarks are obscured by fog, sound is the only medium by which warning signals can be conveyed to mariners. It has been thought that it might be possible to transmit such signals by means of etheric vibrations; but assuming such intercommunication were established, it would fail in two most essential requirements for assisting the mariner in foggy weather, as it would not give him any information as to the direction from which the warning message came, nor would it tell him how far distant the signalling station was. Further developments may in the course of time remedy these defects, but from present-day knowledge and experience it cannot be said that etheric vibrations are available for fog-signal purposes at sea. In a paper recently read before the Society of Arts, Mr. E. Price Edwards discusses the present position of this question of sound signals and gives some interesting particulars of the trials carried out at St. Catherine's Point, in the Isle of Wight, last summer. From this it appears that for many years past sound-producing instruments of various kinds have been employed for uttering warning sounds at points of danger on our coasts, and that constant efforts have been made to develop instruments yielding sounds of great loudness and penetrating power, so as to overcome the numerous obstructive influences affecting the propagation of sound through the atmosphere. The instrument which has proved most effectual for this purpose is the siren, sounded by means of air forced through it at a pressure of about 40 lb. on the square inch. It is used in the form of a double cylinder, one cylinder fixed, the other (inside it) rotating, each cylinder having longitudinal slits corresponding in number and area, through which, as often as they coincide, the air passes. In the trials at St. Catherine's, two flat circular discs with radial slits were tried, with very satisfactory results; but this arrangement involves a separate motor to rotate the movable disc, whereas the rotation of the cylinder siren is effected by the air pressure which produces the sound. It is considered that some loss of power and a more or less defective blast result from the

self-driving arrangement, and that the use of a separate motor will remedy these defects. The trials referred to were made with various forms and sizes of siren and several instruments sounded on the reed principle, the result being that the reed instruments proved greatly inferior to the siren instruments in loudness and penetrating power. It is contended by some that the reed principle as applied for the production of loud sounds has never yet been done justice to, and that with proper development a reed instrument could be made to yield sounds as powerful and penetrating as those of the siren; but, as Mr. Price Edwards points out, the reed instruments tried, and which were supposed to be the most effective types of that form of sound producer in existence, were not able to approach the sirens as regards efficiency for coast fog-signal purposes. If a reed instrument could be brought up to an equality with a siren in respect of sound power, it would probably be more economical than a siren in working. The question of trumpets received some special consideration at St. Catherine's, a new form of trumpet designed by Lord Rayleigh having been experimentally tried there. Lord Rayleigh had observed that with the conical trumpets of circular section usually employed there was a liability to some interference of the sound waves issuing from the mouth, caused by the difference in distance of the nearest and furthest parts of the mouth, whereby the waves were likely to get out of step and thus cause interference. He also pointed out that a good deal of sound was sent to the zenith from the mouth of circular section, which sound was certainly wasted. To remedy these defects, Lord Rayleigh's idea is to make the horizontal diameter at the mouth only half the length of the sound wave generated by the sounding instrument, and that the vertical diameter should be elongated to two wave-lengths or more, thus producing a mouth of elliptical section. The tendency for the waves issuing from the mouth to get out of step would thus be reduced to a minimum, and the narrowness of the mouth at top and bottom would offer but little scope for the sound to be projected upward or immediately downward. So far as the trials went, Mr. Price Edwards tells us that the effects produced were most encouraging, and it is now intended to set up this elliptical trumpet for practical trial at a fog-signal station. The mushroom form of trumpet for an all-round signal has been largely used for lightships. Instead of a long horizontal trumpet, or a vertical one with the head bent over (capable of being turned in any direction), the trumpet is fixed vertically with its mouth directed upward. Just above and in the centre of this open mouth is fixed an inverted cone, and the sound issuing from the trumpet strikes the curved sides of the cone and is reflected out with equal force all round the horizon. The trials made with this form of trumpet showed that it was well adapted for the purpose for which it had been designed.

But however powerful and characteristic the sound-producing instruments may be, the conditions of the atmosphere have very much to do with their effectiveness. An opposing wind, as is well known, shortens the range of penetration of the most powerful sound. An instance is given by Mr. Price Edwards when the sound of a siren was on one day heard for a distance of more than twenty miles, while on another day, with a little opposing wind and a noisy sea, the sound of the same instrument was not heard beyond a distance of one mile and a quarter. Fortunately, when sound signals are most needed, viz. in foggy weather, obstructive influences seldom occur; the air is generally still, the sea quiet, and a homogeneous condition as regards temperature and moisture exists, all of which conditions are favourable for the propagation of sound. It does not seem at all probable that the acoustic clouds of Prof. Tyndall are formed when fog prevails; indeed, they appear to want hot sun, causing evaporation from the sea surface, which produces areas of varying temperature and density. Two remarkable phenomena have been experienced in connection with the experiments at St. Catherine's for which no satisfactory explanation is yet forthcoming. In the one case it was found that at times there was a sort of hiatus in the passage of the sounds. Thus the observers on board the Trinity yacht *Irene* would be in full hearing of the sounds at a mile distance from the instruments. On proceeding out, the sounds would very soon fall away in strength until at a distance of between two and three miles they would be very faintly heard or lost altogether. Proceeding further out on the same line of bearing, the sounds would be gradually recovered, until a little beyond three miles they would again come into full hearing and be carried as loud and distinct sounds for a considerable distance. The question is, what becomes of the lost sound, and what is the influence which renders the area in question "a silent area"? The phenomenon apparently does not occur frequently, for very many times the observers went over the same space without experiencing any such hiatus of sound. Mr. Price Edwards suggests that to solve the question prolonged and continuous observation would be necessary in all parts of the sea area over which the sounds are projected—at the sea surface, on the deck of a vessel, and at varying distances upward by means of a captive balloon. It is of importance to determine, if possible, the cause of this intermission of audibility, in order that it may be prevented or guarded against when the sounds are being promulgated as official warnings to mariners.

The other noteworthy phenomenon which occurred at St. Catherine's and on previous occasions when sound signals have been tested by observation at sea were the aërial echoes. With a smooth sea and still atmosphere, the direct sounds from the sirens were immediately reinforced by powerful echoes from the sea. Mr. Price Edwards describes them as starting from a point on the horizon corresponding to the prolongation of the axis of the trumpet from which the sound proceeded, and with great rapidity spreading out over the sea expanse as though a scattered army of trumpeters in quick succession sounded their blasts from all parts of the horizon. Carefully timed, the echoes lasted at times for 30 seconds, or ten times as long as the original blast. Prof. Tyndall suggested that "the duration of the echo is a measure of the atmospheric depth from which it comes." If this be so, the length and strength of the echoes might afford a general indication of the relative penetrating power of the sounds of different instruments. With a disturbed atmosphere and an agitated sea surface, the echoes were very short or not heard at all. It is noteworthy that both the silent area and the aërial echoes occur chiefly in quiet weather, and that disturbance of air or sea appears to be antagonistic to their manifestation.

An important conclusion appears to have been arrived at in regard to the most suitable note pitch for the blasts of sirens or reed horns. In fog—as has been stated—the meteorological conditions are usually equable, and when such is the case a low-pitched note is found to be more effective than a high-pitched one; on the other hand, when air or sea is disturbed, the higher pitched notes seem to be rather less obstructed by the opposing influences, although the advantage is not very great. Having regard to the fact that the sounds are only required for use in foggy weather, a low-pitched note of about 98 vibrations per second (which is that which was heard plainly more than twenty miles away) is perhaps the best for the blasts of a siren fog signal. In this connection it should be mentioned that in order to obtain the best effect from an instrument it is essential that the note given by the sound producer should, if possible, be in unison with the proper note of the associated trumpet, otherwise the issuing sound is apt to be gruff and discordant.

SEA TEMPERATURE AND SHORE CLIMATE.

IN Mr. W. N. Shaw's paper "On the Seasonal Variation of Atmospheric Temperature in the British Isles" (*Proc.* Roy. Soc., vol. lxix., pp. 61-85), it is stated that it seems "probable that the ocean plays a paramount part in the causation of the second-order temperature effect which we experience in these islands. . . . Whether this variation of the temperature of the water which surrounds these islands is the cause of the atmospheric second-order variation, or whether it is only another effect of the same fundamental cause, does not appear, but in view of the fact that the marked second-order effect is not seen at Continental stations, it would seem not unlikely that the ocean temperature is the immediate cause of our second-order periodic temperature variation. . . . All the successive stages of temperature change are delayed by the effect of the sea. . . . The effect of the sea is to delay the seasons." Of course, it is a very old belief that the vicinity of the sea affects the temperature of a climate, moderating the heat of summer and the cold of winter, but the ideas on the subject have been of the usual vague popular character. What is curious is that it has taken so long to initiate some investigation designed to discover what may be the nature of the relationship between the temperature of the sea and that of the air over the adjacent land. Although the North Atlantic is the most frequented of the great oceans,

very little has thus far been accomplished in discussing its variations of temperature month by month throughout the year; indeed, the region between the 50th and 60th parallels, from our islands across to Labrador, has been almost wholly neglected. Some years ago, the Meteorological Office published mean results for four months; the Deutsche Seewarte has made a separate discussion of each of a number of 10°-squares; and the Copenhagen Institute annually supplies information for the far north, mainly on the routes from Denmark to Iceland and Greenland. These are the principal contributions to our knowledge of Atlantic sea temperature.

The Meteorological Council has now made a new departure in this matter. In connection with the publication of the monthly pilot chart of the North Atlantic and Mediterranean, the cooperation of the captains and officers of the Mercantile Marine has been enlisted to promptly supply daily records of sea temperature during their voyages. A gratifying response resulted in the return of more than 2500 ocean temperatures for the month of January last, and 2750 for February. This mass of valuable information has been grouped in spaces of 2° of latitude by 2° of longitude and means obtained. The results between 30° and 60° N. form the new feature of the pilot charts. Those for January appear on the April chart, and those for February on the May chart. In addition to the means, the variations from the averages of a long series of years are also shown, and lines are drawn separating the regions of excess and of defect. Generally speaking, in January the water was a degree or two colder than usual from Ireland down the face of the Bay to Portugal and thence westward across the Atlantic, while further north, from about the 20th meridian westward, the values were nearly all in excess. In February nearly the whole area was colder than during the preceding month, but compared with the February normals the region of excess was much more extensive than in January. The relatively cold water south-westward from the British Isles had, however, expanded westward to about 30° W. Close inshore the fall of temperature was very marked—off Eastbourne, for instance, it was 44° in January, an excess of 3°, while in February it was only 37°, a defect of 3°. Here we have the commencement of an investigation which, if continued, and improved as may be found necessary, should be fruitful of the most useful results. At present, with only the bare ocean results presented to us, it is not easy to explain what effect should be produced ashore. We know that the air temperature over the British Isles during last January was above the average to the extent of about 2°, while February was nearly 4° too cold, the coldest month for seven years. What part did the temperature of the ocean play in influencing the mildness of the one or the coldness of the other month?

With only these first charts before us, it is obviously impossible to form a just conception of the very complicated problem which requires solution. We must wait for a consecutive series of such charts and examine closely the variations disclosed month by month at sea and on land. It may be that the effect produced on our air temperature by the changes in that of the sea to the west-ward and south-westward is an indirect and not a direct result. The prevalence of winds from particular quarters for any length of time, and the cold or warm ocean surface currents which they set up, the movements of weather systems, &c., must be borne in mind. From the monthly pilot charts it is clear that at times the Gulf Stream fails to reach our shores owing to the existence of a stronger opposing flow. It has been advanced by Dr. Emil Lesshaft, in his paper "Der Einfluss der Wärmeschwankungen des Norwegischen Meeres auf die Luftcirkulation in Europa" (*Meteorologische Zeitschrift*, Band xvi.), that the paths followed by atmospheric disturbances are associated with the temperature of the sea water, and if that should prove to be the case we must consider first of all the temperature of the Atlantic and the march of weather systems, and then the effect the latter produce on our climate. The permanent Atlantic anticyclone maintains its position over a part of the ocean where there is only a slight variation of sea temperature, but its outer limits expand or contract enormously, at times stretching northward as far as Iceland and Greenland, especially in the month of May, when a broad belt of Arctic water flows southward beyond our western coasts. With our present knowledge we can only conjecture as to the causes of these variations, but the information about the sea temperature now becoming available may, perhaps, help us to arrive at a better idea of the forces at work. As the observations become more numerous, would it be possible to issue weekly results of sea temperature?

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ON Thursday next, June 5, the Sir John Cass Technical Institute, Aldgate, will be formally opened by the Right Hon. Lord Avebury, F.R.S.

WITH the object of creating interest in science teaching and nature-study in Southampton and the district, a conference will be held at the Hartley College, on June 14, together with an exhibition of home-made and other simple scientific apparatus. It is felt that much useful work is being done, the character of which is not generally known, and that teachers should be afforded an opportunity of comparing methods and becoming acquainted with that which the experience of others has proved to be of value. A preliminary meeting was held on May 10, when Dr. H. E. Armstrong, F.R.S., gave an address on the chief points to be borne in mind in early lessons in science. As he has often remarked before, science must not be taught so much on account of its matter as for training in scientific methods of work and reasoning. What is desired is that habits which characterise the true worker in science should become general habits, with the object of developing the practice of the best mental faculties.

THERE are many signs that the movement for reform in the teaching of mathematics will have a decided influence upon the scope and character of elementary geometry in schools. Several public examining bodies have lately had the subject under consideration, and changes in the direction of reform are likely to be instituted. The regulations just issued for the Oxford Local Examinations next year contain an announcement referring to the examinations in geometry which will have a very decided effect upon the scope and method of the subject in secondary schools. The notice reads as follows:—"Questions will be set so as to bring out as far as possible a knowledge of the principles of geometry, a smaller proportion than heretofore consisting of propositions as enunciated in Euclid. Any solution which shows an accurate method of geometrical reasoning will be accepted. No question will be set involving necessarily the use of angles greater than two right-angles. Geometrical proofs of the theorems in Book ii. will not be insisted upon." It is evident from this announcement, and the deliberations of other examining bodies and teachers, that Prof. Perry selected the right "psychological moment" for directing attention to the irrational ways of approaching geometry in schools and the need for recognition of work better adapted to modern needs. As both examiners and teachers are in general sympathy with his desire to get rid of artificiality in mathematics, we may expect that the time will come when geometry will not be commenced, as it is in many schools to-day, by learning Euclid's definitions, postulates and axioms and reading propositions, but by the intelligent use of compasses, protractor and scale.

IN introducing the Education Vote in the House of Commons on Monday, Sir John Gorst directed attention to some of the changes and developments which have taken place in the administration of the Board of Education. Schools of science and other secondary day schools inspected by the Board are to have block grants instead of payments by results of examination, the grants being assessed every three years. By this system, it is hoped that all inducement to cram will be removed. Both in the administration of the Parliamentary grant and in the inspection of schools the Board of Education will aim at encouraging originality and variety. The hope was expressed that the time would be far distant when those who had to administer the public funds of this country and to carry out the provisions of the Act with regard to secondary schools forgot the enormous danger of interfering to produce uniformity of system, and that they would give every encouragement to variety and independence. Referring to the Royal College of Science—one of the two Government colleges in London which are entirely under the management of the Board of Education, the other being the Royal College of Art—Sir John Gorst said:—"The vote for this school, which is a very advanced science school, has been increased in the present year by 1000*l.* for the purpose of enabling work to be continued—begun by Sir Norman Lockyer—respecting the relation of certain precedent phenomena in the sun observed through the spectroscope to the subsequent rainfall in India and Australia. No certain law has yet been established, but if the research is successful it will have enormous beneficial economic effects, both for India and Australia."

Other subjects referred to were the educational work of the Victoria and Albert Museum, the new advisory spirit in which the inspection of schools is to be carried on, and the provision by local authorities of a better system of training teachers than at present exists.

Two pamphlets referring to the purpose and programme of the Faculty of Commerce of the University of Birmingham have been received. The Faculty will begin its work in October next and there will be matriculation examinations on June 2 and September 15. In the course of his prospectus, Prof. Ashley remarks that the object of the work to be carried on by this department of the University is the education, not of the rank and file, but of the officers of the industrial and commercial army: of those who, as principals, directors, managers, secretaries, heads of departments, &c., will ultimately guide the business activity of the country. The Faculty represents the first serious attempt to provide training of this kind, though every year shows the need of it. Prof. Ashley points out that the marked acceleration of the speed of industrial and commercial change, the application of science to machinery involving more frequent changes in manufacturing processes, and the extension of means of communication, call more and more for mental flexibility, alertness and adaptability on the part of traders. But such qualities are certainly not likely to be stimulated by early absorption in the subordinate routine of a particular occupation. There is, however, some chance of promoting them by courses of instruction which shall accustom the future trader to survey a wide range of industrial undertakings, to watch the development of the world's great markets, and to estimate the resources and capabilities of other nations. The curriculum which has been drawn up for the three years' course leading to the degree of Bachelor of Commerce in the University of Birmingham comprises studies which fall mostly into four main categories:—(1) languages and history; (2) accounting; (3) applied science and business technique; (4) commerce. The purpose of the scientific subjects included in the course is not to make men scientific experts. Its aim is (*a*) to make their business more interesting to them; (*b*) to enable them to follow the general movement of technological progress, and to realise the directions in which changes of process are probable or possible; (*c*) to show them when they ought to call in an expert, and how much weight they should attach to his opinion.

SCIENTIFIC SERIALS.

Journal of Botany, May.—Mr. Rudolf Beer describes a rare and remarkable conidia-bearing fungus, *Coemansiella Alabastrina*, which has only been recorded twice before. The conidiophore begins like Eruotium, but the sterigmata are few in number and grow out forming a circlet of arms; from each of these a series of conidia is cut off on the upper side. The conidia are fusiform and pointed at both ends. Chlamydospores and other conidial bodies were obtained in the culture, but no traces of perithecia were observed.—Mr. Pugsley has devoted considerable attention to the British "capreolate" Fumitories and submits the following classification:—Subsection 1. *Eucapreolatae.* Bracts as long as pedicel; pedicel recurved; fruit pendulous, narrow at the base. (1) *F. capreolata*, L. (=*F. pallidiflora*, Jord.). (2) *F. purpurea*, Pugsley, which refers to certain English plants named as *F. Boraei*, Jord., but differing from Jordan's original discription. Subsection 2. *Murales.* Bracts shorter; pedicels erect; fruit without a neck. (3) *F. muralis*, Sond. (includes *F. Boraei*, Jord.). (4) *F. confusa*, Jord.—Dr. Rendle describes three new species of Convolvulus from South Africa, a Convolvulus, and two Ipomæas which we regret to find are named after the collectors instead of receiving distinctive names.—Mr. G. C. Druce gives a list of Anglesey and Carnarvonshire plants and Mr. J. Hunter records North Donegal mosses.

Bulletin of the American Mathematical Society, vol. viii. (2) No. 7, April.—S. E. Slocum, on the transformation of a group into its canonical form. A discussion of the Lie group defined by $X_1=\delta/\delta x_2$, $X_2=x_2\delta/\delta x_2+\delta/\delta x_1$.—O. Dunkel, some applications of Green's theorem in one dimension. The theorem thus designated is an integral relation deduced from a linear differential equation and its adjoint. Some applications follow.—V. Snyder, on the forms of quintic scrolls.—E. V. Huntingdon, simplified definition of a group. This interesting paper defines a group as an assemblage of elements satisfying the three postulates: (1) Given any two elements a, b, there is an element x such that $ax=b$; (2) there is an element y such that $ya=b$; (3) if a, b, c, ab, bc, and either $(ab)c$ or $a(bc)$ are elements of the assemblage, then $(ab)c=a(bc)$. A finite group requires the additional postulate that the assemblage shall contain only n elements.—L. P. Eisenhart, on isotropic congruences.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, May 23.—Prof. S. P. Thompson, president, in the chair.—Mr. T. C. Porter showed a lecture experiment on the ebullition of rotating water. If the water in a beaker, having approximately vertical sides, be caused to rotate about an axis concentric with the vertical geometrical axis of the beaker, it is obvious that in any horizontal section of the water the pressure is least in the centre and increases from the centre outwards. If the temperature of the water is just below boiling point and heat is supplied to it whilst it is rotating steam is formed only in the region of least pressure, and a gaseous core is produced. The rotation can be given to the water by stirring it with a glass rod covered with a piece of india-rubber tubing, and maintaining the stirring motion during the act of withdrawal of the rod. Some curious phenomena are shown by the column of steam, if the water is first stirred and then left to come to rest whilst the heating is continued. At first there is a markedly concave surface to the water in the beaker, and the column of steam is practically continuous from base to summit. After this stage pulsations set in. Pulsations can also be produced by stirring cold water in a beaker-shaped jar, having a small hole in its bottom through which a stream of air-bubbles can be blown. The forms of the steam columns in some cases present a likeness to those of solar prominences, and Mr. Porter suggested that the immediate cause of the latter might be the diminution of pressure on the sun's surface at, or near, the centre or centres of depressions caused by violent cyclonic disturbances in the solar atmosphere.—Mr. C. V. Boys exhibited a small heat engine in which rotating water evolved steam without ebullition.—A paper by Mr. J. A. Erskine on the conservation of entropy was read by the secretary. Heat energy may be expressed as the product of two factors—a quantity factor, entropy, and an intensity factor, temperature. The conservation of entropy holds in thermodynamics when dealing with reversible processes, and is analogous to the conservation of other quantity factors such as momentum, moment of momentum, and electric quantity. The author shows the completeness of the analogies by considering Carnot cycles carried out on electrostatic and hydraulic engines. Prof. Wiedeburg has proposed to extend the doctrine of the conservation of entropy to irreversible processes by introducing a new quantity analogous to electric resistance.—A paper by Sig. G. Giorgi on rational units of electromagnetism was read by Mr. Price. Mr. Price prefaced the reading of the paper by saying that both Prof. Fleming and Prof. Fessenden had advocated a partial change of units which would leave the most important ones unchanged, and the method employed by the author was similar to that adopted by Prof. Fessenden. The author starts with a set of three equations, which contain explicitly the four concrete units of E.M.F., M.M.F., electric current and magnetic current, together with that of activity, and considers them as fundamental in electromagnetism. Two fundamental units are required to express these quantities, and their product must reproduce the mechanical unit of activity. If the watt is assumed as unit of activity, there are two units ready made, the volt and the ampere, which satisfy the condition and may be considered fundamental. All concrete units in electricity and magnetism can be expressed in terms of these and the second as unit of time. In order to complete the system, a unit of length is required. The metre and kilogramme are consistent with the watt, and putting them together with the units enumerated in the paper, the author has built up an absolute metre-kilogramme-second system which comprises electric, magnetic and mechanical measures in a consistent frame.

Chemical Society, May 15.—Dr. W. H. Perkin, F.R.S., vice-president, in the chair.—The variation with temperature of the surface-tensions and densities of liquid oxygen, nitrogen, argon and carbon monoxide, by Messrs. E. C. C. Baly and

F. G. Donnan. The measurements were made by a modification of Ramsay and Shield's method between 70° and 90° absolute, and the results were found to be in accordance with the view that these liquids consist of non-associated molecules. The critical temperatures deduced from these observations are in agreement with those directly determined for oxygen and nitrogen, but not with the values assigned to argon and carbon monoxide for this constant.—Comparison of bromonitrocamphane with bromonitrocamphor, by Dr. M. O. Forster. The action of various reagents on bromonitrocamphor has been examined in the hope of isolating derivatives of the latter substance analogous to those obtained from bromonitrocamphane, but in most cases the reactions proceed either further or in a different sense.—$\alpha\alpha$-Benzoylnitrocamphor and $\alpha\alpha$-benzoyliodocamphor, by Dr. M. O. Forster and Mr. E. A. Jenkinson. A description of these substances and several of their derivatives is given illustrating the peculiar $\alpha\alpha'$-isomerism of substituted camphors.—2 : 4-Dibromo-5-nitro- and 2 : 4-dibromo-3 : 5-dinitrotoluenes and their behaviour on reduction, by Mr. W. A. Davis. These substances are produced by the direct nitration of 2 : 4-dibromotoluene, and on reduction furnish respectively 4 : 6-dibromo*meta*toluidine and *sym.*tolylene diamine.—The purification of hydrochloric acid from arsenic, by Dr. Thorne and Mr. E. H. Jeffers. The purification of hydrochloric acid to be used in testing for arsenic may be accomplished by digesting in it pieces of bright copper gauze, so long as these become stained by the deposition of arsenic on their surface.—The radioactivity of thorium compounds, and the cause and nature of radioactivity, by Prof. Rutherford and Mr. Soddy. Thorium, from which the radioactive substance Th.X has been separated, regains its activity after a time, while that of Th.X. slowly disappears. This production and disappearance of activity is not affected by any known agents, and proceeds independently of the physical and chemical conditions of the molecule; the authors believe that the source of this energy is to be found in a chemical change producing new types of matter.—The radioactivity of uranium, by Mr. F. Soddy. Prof. Rutherford has already shown that uranium exhibits a dual radiation, one, α, having little action on a photographic plate and a second, β, almost inactive to the electrometer under ordinary conditions. The author now finds that the substance Ur.X isolated from uranium possesses only the β-radiation, the α-effect being retained by the parent substance.

Royal Meteorological Society, May 21.—Mr. W. H. Dines, president, in the chair.—Captain D. Wilson-Barker read a report prepared by Mr. Dines and himself on the wind force experiments which had been made on H.M.S. *Worcester* off Greenhithe and at Stoneness Lighthouse, 817 yards from the ship on the north bank of the river. These experiments were in continuation of those on the exposure of anemometers at different elevations which were carried out on the *Worcester* a few years ago. All the observations were made with the pressure-tube anemometer. The broad general result is that the lighthouse experiences steadier and stronger winds than the *Worcester*, the velocity being about 6 per cent. greater, notwithstanding the fact that the elevation is less than half, but that in both positions the extreme velocities reached in the gusts are about equal.—Dr. H. R. Mill read a paper on the Cornish dust fall of January, 1902. When the west of England newspapers of January 24 announced falls of "pink snow" and "muddy rain" in several parts of Cornwall and South Wales, it seemed to the author possible that fresh light might be thrown on what is at present the chief object of progressive meteorology, viz. the movements of the upper air. He therefore took steps to collect as much information as possible from the whole of the district, and found that the phenomenon was reported from seventy-five different places in the south-west of England and Wales. These were all south of a line joining Milford Haven and Chepstow, and west of the meridian of Bath. By means of a map, Dr. Mill showed that four separate areas were visited by the dust between January 21 and 23, viz. (1) Cornwall, 1400 square miles; (2) North Devon, 150 square miles; (3) Milford Haven, 50 square miles; and (4) Bristol Channel, 600 square miles. The dust appears to have been confined mostly to low rather than high ground, for none was reported to have fallen on the Mendip Hills, Dartmoor, Exmoor and the Welsh mountains. The observations show that January 22 was undoubtedly the day when most falls occurred and that the colour of the dust was yellowish or brownish. From a consideration of the meteorological conditions at the time and for several days before, the author is inclined to believe that the evidence points to the dust having been transported in the upper air from the African deserts.

Edinburgh.

Royal Society, May 5.—Prof. Geikie in the chair.—A paper was communicated by Prof. Beattie on the leakage of electricity from charged bodies at moderate temperatures (part iii.). The paper described a great variety of experiments in which such substances as common salt, lithium chloride and potassium bichromate, when laid on zinc and sprinkled with iodine or bromine, and then raised to a temperature between 300° and 350° C., caused electrification of the surrounding atmosphere of air, coal gas, oxygen or carbonic acid gas. Hydrogen was not electrified under similar conditions. The effects differed from those produced in other ways. Thus, in addition to the well-known electrifying properties of flames and their fumes, there seem to be three distinct methods of obtaining an electrified gas by heating: (1) by oxidation or deoxidation as in the atmosphere drawn from the neighbourhood of oxidising or deoxidising metals (Schuster), (2) by driving off a gas which carries a charge with it as in the case of the gas obtained by heating potassium permanganate (Townsend), (3) by the methods described in the present paper.—Prof. MacGregor communicated a paper by the late Prof. C. Piazzi Smyth, Does the spectrum place of the sodium lines vary in different azimuths? The paper bore the date May 25, 1882, and the investigation had been suggested by Prof. Tait, among whose papers the manuscript had been found. The apparatus used consisted of a Rutherford grating with 17,296 lines to the inch, the necessary collimator and telescope, and an end-on vacuum tube containing sodium vapour. The whole was set up on a rotating table, and measurements of the positions of the D lines were made in various azimuths. The results were negative. An idea of the sensitiveness attained may be gained from the statements that the two principal D lines were separated by 266 micrometer divisions, and that the probable error of observation was two of these divisions.

Paris.

Academy of Sciences, May 20.—M. Bouquet de la Grye in the chair.—On the optical arrangements necessary for remedying the visual troubles in cases of keratoconia, by M. J. Janssen. A description of a lens system by means of which the effect of this disease can be almost entirely compensated.—On the composition of the ashes projected from Mont Pelée on May 3, 1902, by M. Michel Levy. Andesine and hypersthene were recognised as the chief constituents of the volcanic ash.—On the spermatogenesis of the diptera of the genus Sciara, by M. Alfred Giard. The emission of the spermatic elements in Sciara is accompanied by phenomena nearly as complicated as in the Cephalopods. There is no production of a capsule forming a true spermatophore.—The addition of hydrogen to ethylenic hydrocarbons by the method of contact, by MM. Paul Sabatier and J. B. Senderens. The catalytic action of reduced nickel and copper in causing the addition of hydrogen to unsaturated hydrocarbons has been extended to propylene, trimethylethylene, hexene and octene. Propylene mixed with hydrogen in excess is readily transformed by reduced nickel at 160° C. into propane; copper behaves similarly, but the reaction is slower. Trimethylethylene is similarly converted into pure methylbutane in the presence of nickel, but copper is without action in this case. It has been found that copper and nickel are equally capable of effecting the addition of hydrogen in the case of ethylene derivatives containing the grouping $=CH_2$, but that compounds of the type $R.C{=}CR'$ do not add on hydrogen under the action of copper. Application is made of this to the case of limonene, with the result that the formula ordinarily attributed to it, representing it as containing a $=CH_2$ group, is confirmed.—On the arithmetical properties of entire and quasi-entire functions, by M. Edmond Maillet.—On the repulsive force and electrical actions emanating from the sun, by M. H. Deslandres. A criticism of the views of S. Arrhenius, with some remarks on the nature of nebulæ.—On the constitution of matter and spectroscopy, by M. B. Eginitis. The author regards the elimination of air lines in Schuster and Hemsalech's work on spark spectra as being chiefly due to the metallic vapours produced.—The action of light on precious stones, by M. Chaumet. A connection is shown to exist between the

fluorescence of a diamond under violet light and its lustre under ordinary artificial light. In the case of a yellow diamond, after a short exposure to violet light, the colour changed from yellow to a dark brown; after twenty-four hours, however, the diamond recovered its original colour and lustre.—The volumetric estimation of iodides in the presence of chlorides and bromides, by M. V. Thomas. In dilute solution, in the presence of an excess of a thallic salt such as the chloride, the whole of the iodine in the iodide is set free. Test analyses are given showing the accuracy and range of the method.—On the action of sulphites on the nitroprussiates, by M. Juan Fages.—On a method of gradual synthesis of aldehydes, by MM. L. Bouveault and A. Wahl. Nitroisobutylene, reduced by aluminium amalgam or by zinc dust and acetic acid, is converted into isobutyric aldoxim. Nitrostyrolene, $C_6H_5-CH=CH-NO_2$, was found to undergo a similar change on reduction by either of the above-mentioned reagents, giving phenylacetaldoxime.—The sexual elements and fertilisation in Pterocephalus, by MM. Louis Léger and Octave Duboscq.—On the destruction of certain noxious insects in agriculture and especially the wire worm in the plum-tree, by M. J. Laborde. The composition and mode of application of an insecticide is given which has been proved by experiment to be efficacious in combating the parasite.—*Sarcocystis tenella*, a parasite of man, by M. Paul Vuillemin.—On *Kinkeliba* and its botanical origin, by MM. E. Perrot and G. Lefèvre. Kinkeliba is an arborescent plant the leaves of which are employed by the natives all over western Africa as a medicine, and which merits a complete therapeutical study. It is identified as *C. micranthum*.—On the tectonic relations between Greece and western Crete, by M. L. Cayeux.—A point of the geology of the neighbourhood of Bayonne, by M. R. Chudeau.—On a principle of rational classification of gorges cut by water courses, by M. Jean Brunhes.—The microbiological study of the steeping of flax, by M. L. Hauman. The aërobic rotting of flax has been accomplished with pure cultures of various organisms, including *Penicillium glaucum*, *Aspergillus niger*, *Botrytis cinerea*, *Bacillus coli communis* and others. The process appears to consist essentially in the fermentation of pectic bodies, considerable quantities of which are present in the original flax, but of which traces only can be found after fermentation. The rotting of flax is thus a purely biological process which is accomplished by means of the bacteria and moulds of the soil. The disintegration is due to the disappearance of the tubes of the young tissues filled with pectic substances which separate the fibro-vascular bundles.—The influence of lecithin on the development of the skeleton and of nervous tissue, by MM. A Desgrez and Aly Zaky. It is shown that the increase in weight of animals receiving lecithin is not due to an abatement of nutrition, but is due to the phosphoric acid retained by the organism, under the influence of the lecithin, being normally utilised for the development of the osseous and nerve-cells.—The vaccination against pasteurelloses, by MM. Joseph and Marcel Lignières. The name pasteurelloses is applied to a group of diseases of the same type, including typhoid fever and pneumonia of the horse, chicken cholera and hæmorrhagic septicæmia of the sheep, ox and pig. It has been proved by experiment that it is possible to prevent these diseases by a process of vaccination.—The etiology of the canker and gum in fruit trees, by M. F. P. Brzezinski.

DIARY OF SOCIETIES.

THURSDAY, May 29.

Royal Society, at 4.30.—The Minute Structure of Metals and other Plastic Solids: G. Beilby.—The Influence of Varying Amounts of Carbon Dioxide in the Air on the Photosynthetic Process of Leaves and on the Mode of Growth of Plants: H. T. Brown, F.R.S., and F. Escombe.—On the Influence of an Excess of Carbon Dioxide in the Air on the Form and Internal Structure of Plants: Prof. J. B. Farmer, F.R.S., and S. E. Chandler.—On the Structure of the Gills of the Lamellibranchia: Dr. W. G. Ridewood.

Society of Arts, at 4.30.—Western Australia: its Progress and Resources: Hon. J. W. Venn.

Institution of Mining Engineers (Geological Society), at 11.—Working Coal under the River Hunter, the Pacific Ocean and its Tidal Waters, near Newcastle, New South Wales: A. A. Atkinson.—Lead and Zinc Deposits of the Mississippi Valley, U.S.A.: Prof. C. R. Van Hise and H. Foster Bain.—The Campbell Coal-washing Table: Clarence R. Claghorn.—The Mining, Concentration and Analysis of Corundum in Ontario: Dr. W. L. Goodwin.—Re-opening of Hartley Colliery: R. E. Ornsby.—Deposits of Hydroborate of Lime: its Exploration and Refination: Carlos A. Lynes Hoskold.—Remarks on Mr. M. Walton Brown's "Report on Mechanical Ventilators": Prof. A. Rateau.

FRIDAY, May 30.

Royal Institution, at 9.—The Electronic Theory of Electricity: Prof. J. A. Fleming, F.R.S.

Institution of Mining Engineers (Geological Society), at 10.30.—The Training of Industrial Leaders: Prof. J. Wertheimer.—Smelting in British Columbia: W. Denham Verschoyle.—Treatment of Low-grade Copper-ores in Australia: J. J. Muir.—The Tarkwa Gold field, West Africa: A. R. Sawyer.—Gold-dredging: T. Ross Burt.—Gold-dredging in Otago, New Zealand: F. W. Payne.—Electric Traction on Roads and Mineral Railways: W. R. Cooper.—The Analytical Valuation of Gas-coals: G. P. Lishman.

Epidemiological Society, at 8.30.—A Doubtful Case of Hæmorrhagic Smallpox: S. Murphy and Dr. Klein, F.R.S.—An Outbreak of Syphilis in an Indigenous Tribe in India: Dr. L. Rogers.

MONDAY, June 2.

Institute of Actuaries, at 5.

Geologists' Association, at 8.—On a Peculiarity in the Course of Certain Streams in the London and Hampshire Basins: H. J. Osborne White.—Note on the Occurrence of *Microtus intermedius* in the Pleistocene Deposits of the Thames Valley: M. A. C. Hinton and G. White.

CONTENTS.

THURSDAY, JUNE 5, 1902.

THE POPULAR HUXLEY.

Thomas Henry Huxley. By Edward Clodd. Pp. xiii + 226. (Edinburgh and London: William Blackwood and Sons, 1902.) Price 2*s*. 6*d*.

DR. RICHARD GARNETT has described Huxley's work as "that of the populariser; the man who makes few original contributions to science or thought, but states the discoveries of others better than they could have stated them themselves." I am disposed to think that the picture my friend Mr. Clodd has drawn with practised dexterity will rather confirm than dissipate this inadequate judgment. On the last page of this volume he writes, with perhaps a touch of remorse:—"To regard Huxley as a compound of Boanerges and Iconoclast is to show entire misapprehension of the aims which inspired his labours." I entirely agree; but the words might have been added to the title-page without doing serious injustice to what follows.

With such a Huxley I must frankly confess I have very little sympathy. I prefer the one which, with much critical insight, Mr. Chalmers Mitchell has presented to us "in his admirable monograph."

Huxley was so big a man in my judgment that his real merits can well afford to bear the brunt of dispassionate criticism. Disagreeing as I do with Dr. Garnett, I go farther, and think that as a "populariser" Huxley was by no means always successful. And Mr. Clodd supplies the reason in "that passion for logical symmetry" which appears to me often Huxley's besetting sin.

I only echo the opinion of competent judges in saying that he will be always clearly recognised as occupying a foremost place amongst English scientific men of the nineteenth century. He rescued animal morphology from the deductive method, and firmly established it on an inductive basis. In doing this there is scarcely any part of the animal kingdom which he did not illuminate by original and brilliant work. And he applied the theory of evolution with masterly insight to the explanation of the facts. All this was, however, only accomplished in the most cautious way, and was the result of patient observation and study. An examination of his published researches will show that he never advanced a step without making the ground firm beneath his feet.

In his more popular writings I am bound to say that I often fail to find the same qualities. Facts and knowledge were taken frequently at second hand, and were not the acquisition of his own personal labour. No one can deny the literary skill with which they were used. But the habit which grew upon him of pushing home remorselessly the conclusions he drew from them often landed him in very dubious positions. This is the more singular as he saw the danger in the case of mathematical reasoning, and rightly insisted that "what you get out depends on what you put in."

Huxley was firmly imbued with what is ordinarily called a "materialistic" conception of the universe. I think myself that this is probably a true view, though I confess I am getting rather at sea about "electrons" and "ions." Nor am I at all disposed to agree with Principal Rücker that atoms are more than a physical hypothesis. I do not admit that Prof. "Britschli" has produced "a substance which simulates protoplasm" or has done more than give us some pretty examples of surface tension. I do not see even the beginning of a materialistic theory of protoplasm. This, however, was what Huxley attempted in the lecture on the "Physical Basis of Life," of which I see a cheap reprint is about to be issued. Mr. Clodd summarises it as if its contents were accepted scientific truths. But this is far from being the case, and I should myself be in great difficulty if they were presented to me in the examination room.

Huxley—to take only one out of many disputable assertions—after speaking of "the dull vital actions of a fungus," states that its "protoplasm is essentially identical with and most readily converted into that of any animal." Further on he puts the idea into a more picturesque form and speaks of "transubstantiating mutton into man." Except the definition of a crab attributed to the French Academy, I call to mind no statement so compact of error. Every physiologist knows that between the protoplasm of a sheep and that of the human being who consumes it there is a whole series of compounds which bear no resemblance to protoplasm at all. The animal has to build itself up from lifeless matter just as the plant has, only it mostly uses more complex molecules. It is no doubt true that a particle of fungoid differs in no appreciable physical respect from one of human protoplasm, yet the former will never emerge from the fate of the humble mushroom, while the other may be instinct with the thoughts of a Prime Minister. It may be that the difference is a function of molecular arrangement. If so it is of an order entirely different from anything chemistry presents us with. The fact is that protoplasm is not in any intelligible sense of the word a substance at all, but rather a structure or mechanism. Huxley puts this clearly enough later on in a letter to Herbert Spencer ("Life," i. 127).

Huxley's theological writings seem to me to exhibit defects of the same kind. He did not invent biblical criticism, though one might almost imagine from Mr. Clodd that he did. The argument seems to be this: read the Bible as if it were the *Times* newspaper; then ask yourself the question—Can I accept the statements of the one as literally as of the other? The answer of most persons will be, No. Very well then, Huxley replies:—You are in this position: Christianity is based on the Bible, and my sense of veracity compels me to say that it "vanishes" ("Life," ii. 212), or at any rate "is doomed to fall" ("Essays," v. 142), and some other "hypostasis of men's hopes" will take its place (*l. c.* 254).

But I fail to see the validity of the conclusion. Huxley's analysis of orthodox Christianity is that it is a "varying compound of some of the best and some of the worst elements of Paganism and Judaism, moulded in practice by the innate character of certain people of the western world" ("Essays," v. 142). Without discussing this, it clearly represents Christianity as a product of evolution. There will be, therefore, no new hypostasis necessarily; the moulding will go on and there will be fresh adjustments, as there have been in the past, to higher ethical demands.

I confess I hoped to find in Mr. Clodd's book what I have entirely failed to construct for myself, a consistent and systematic summary of Huxley's teaching in these matters. That he has not succeeded convinces me that the thing is impossible. Huxley's position was avowedly negative; he had no illusions on the subject ("Life," ii. 301). Mr. Clodd says that he "asked the churches to revive" the creed of Micah. I fail to find the passage, or that he did more than recommend that creed as a "work of art." Two years later he wrote:—"That there is no evidence of the existence of such a being as the God of the theologians is true enough" ("Life," ii. 162).

The fact is—and I think Mr. Clodd has failed to bring it out clearly—Huxley's theological and ethical writings are not a gospel, but the revelation of the working of a nature of singular complexity. A heart of warm emotion was in perpetual conflict with an intellect which strove to be the "clear cold logic engine" which he so much desiderated ("Life," i. 198). The late R. H. Hutton, who often showed real insight, hit the mark when he said that Huxley's "slender definite creed in no respect represented the cravings of his large nature," and there was more than sly humour in Bishop Thirlwall's remark on the presence at the Metaphysical Society of "Archbishop Huxley and Prof. Manning." The man's real catholicity of temperament endeared him to his friends and overbore the effect of his cold logic and often petulant agnosticism.

In dealing with biblical or any other ancient documents it is not sufficient to dismiss them because their literal accuracy cannot be sustained. The scientific problem is to ascertain how they came to be evolved by mankind and what is the true meaning behind them. This Huxley rarely did, and in consequence laid himself open to the reproach attributed to Jowett that "he did not consider the literature." Huxley said "the story of the Deluge is a pure fiction" ("Essays," iv. 234). But it occurs in Babylonian literature, and he subsequently followed Suess in giving what is probably its true explanation (*l. c.* 247). He gave himself an excellent example of the true method in his analysis of "the account of Saul's necromantic expedition," which he thought "quite consistent with probability" ("Essays," iv. 291), and he defines in the same essay with luminous precision what may be described as the method of biblical palæontology (*l. c.* 290).

It seems to me that it would be a mistake to take Huxley's theology too seriously. It was essentially an intellectual product and not a working system. Thus he took "the conception of necessity to have a logical and not a physical foundation" ("Life," i. 412). He was above all things masculine and human. In re-reading his "Life and Letters," I am struck with the sanity of his judgments on administrative and political questions. To whatever extreme he pushed his logical conclusions in reasoning, when it came to "business" he was essentially practical. He raised many important questions. That is easy enough even for men of smaller intellectual calibre. What he did with them is that which really interests us. The ethical problem is the one of greatest actual importance. His fundamental position as regards this was a divorce between theology and ethics. "The end of the evolution of theology will be like its beginning—it will cease to have any relation to ethics" ("Essays," iv. 371, 372). But the practical difficulty at once occurred to him—How is the dense mass of human action to be influenced by an appeal to abstract principles? Here is his answer:—"I must confess I have been . . . seriously perplexed to know by what practical measures the religious feeling, which is the essential basis of conduct, was to be kept up, in the present utterly chaotic state of opinion on these matters, without the use of the Bible. The Pagan moralists lack life and colour, and even the noble Stoic, Marcus Antonius, is too high and refined for an ordinary child" ("Essays," iii. 397). "Life and colour"—there you have the problem in a nutshell. When it came to the question of Board School education, he fought for the Bible. According to Mr. Clodd (p. 37), shortly before his death he regretted this, and "came to see" that it was "deplorable." But in 1894 he did "not repent . . . in the least" ("Life," ii. 383), and as to the "highest biblical ideal," he wrote in 1897, "I do believe that the human race is not yet, possibly never will be, in a position to dispense with it" ("Essays," v. 58).

Meanwhile it is interesting to note that he had tried various other solutions. One was obedience to natural law, an old-fashioned precept which traces back to Kingsley and farther:—"The safety of morality lies in . . . a real and living belief in that fixed order of nature which sends social disorganisation upon the track of immorality, as surely as it sends physical disease after physical trespasses ("Essays," ix. 146).

But the "colour" question was insistent, as it must be, and so the moral sense was identified with "an innate sense of moral beauty" ("Life," ii. 305). This was compared with the æsthetic sense, and as with that ("Essays," ix. 80), "evolution accounts for morality" ("Life," ii. 360). This was an intuitional theory which was finally replaced by one that was practically utilitarian. "Of moral purpose I see no trace in nature. That is an article of exclusive human manufacture" ("Life," ii. 268). Mr. Clodd will save me the trouble of enforcing the position by further citations. "The terms 'good' and 'evil' have no meaning till communal life begins. Where there is no society there is no sin. A solitary man on an uninhabited island can do no wrong" (p. 284). I believe it is a moot point whether political economy can exist on an island with two inhabitants. But it seems a little harsh when there is only one to deprive him of such consolation as he may derive from his "innate sense of moral beauty" and bring him down without appeal to the level of the beasts that perish.

The Romanes lecture, which Mr. Clodd admires so much, to me is pathetic, because it is a sort of cry of despair. The cosmic order which we were formerly exhorted to conform to is identified with evil, and this is to be strenuously combated by the ethical principle. But the conflict will be unavailing, and the cosmic order will resume its sway. So after traversing the whole field of ethical exploration we are finally thrown into the arms of Schopenhauer. All this is intensely interesting to anyone who cares for such problems or for the working of a remarkable mind. But helpful or constructive I distinctly say that it is not. I turn to Mr. Clodd and find that he extracts from it "a religion that, coordinated with the needs and aspirations of human nature, would

find its brightest motive and its permanency in an ethic based on sympathy."

Sympathy may explain the altruistic aspect of morality; but I fail to see how it accounts for the "renunciation" of the lower impulses which is characteristic of the highest ethical development. And how for practical purposes is "sympathy" to be infused? My experience of human nature inclines me to think that it requires a more powerful appeal to the imagination than is afforded by a mere academic counsel of perfection of this sort. As I am writing these lines my eye falls on a speech in the daily paper by Viscount Goschen. I quote the following:—

"As a layman he wished, on behalf of the laymen, to express their admiration of the work which was being carried on, and which the clergy were doing in the East-end of London. Thirty years ago, when he was at the Poor Law Board, he made a special study of the statistics of poverty, ignorance and crime at the East-end, and he learned that the miserable breakages of civilisation resorted in their deepest despair to Bethnal Green, and hid themselves there amongst the very poor."

If we dispense with the clergy, have we at present any effective agency for dealing with this sort of problem? I see none, and I am firmly persuaded that no abstract principles would have prevented Huxley substantially agreeing with Lord Goschen.

Mr. Clodd frames a severe indictment against the theology of the last century. It did not lift its voice against the excessive use of capital punishment. I confess I do not see where theology comes in; it is a question of purely civil policy. Sentimentalism apart, the free use of hanging is scientifically arguable. Huxley thought that for "moral cripples and idiots . . . there is nothing but shutting up and extirpation" ("Life," ii. 306). Mr. Clodd complains that theology "still wages bitter war to enforce the teaching of her discredited dogmas; and, to her even greater shame, fans and fosters the spirit of militarism." This would be all very well in a secularist pamphlet, but I fail to see its place in a life of Huxley, even if I thought it just. Huxley's views about the Afghans ("Life," i. 489) show that, right or wrong, he was not wanting in the virile instinct of the normal Englishman.

From my point of view, which is that of a thorough-going evolutionist, I hold it unscientific to array one plane of theology against another which demands a higher ethical standard in practice. It would be as reasonable to complain that *Amphioxus* was unable to take advantage of a Board School education. If we agree with Huxley that theology is "a natural product of the operations of the human mind" ("Essays," iv. 288), Mr. Clodd is simply pointing his sword to his own breast.

Huxley was so transparently honest that no prejudice would blind his eyes to the merit of any agency that made for good, however sceptical he might be as to the basis on which it rested. Orthodoxy could not desire a more touching appreciation than his of "the bright side of Christianity" ("Essays," v. 254). He had even a good word to say of Roman Catholicism in the past ("Life," i. 346). He was deeply impressed with the life of Catherine of Siena. Whatever may have been his own intellectual convictions, life still remained to him "a hopeless riddle" ("Life," ii. 134). That is the utmost positive outcome I can derive from his ethical teaching, and I do not see that Mr. Clodd carries us farther.

W. T. THISELTON-DYER.

A MONOGRAPH OF MOSQUITOES.

A Monograph of the Culicidae of the World. By F. W. Theobald, M.A., F.E.S. 3 vols. Pp. xxvi+815; 42 plates. (London: Trustees of the British Museum.) Price 3*l*. 3*s*.

THIS work has been undertaken chiefly with the object of enabling "medical men engaged in tracing the connection between mosquitoes and human disease to identify and speak with precision of the species implicated." A considerable knowledge of the principles of entomology has now become a necessity in such investigations, and the present work forms an excellent guide and help in the processes of identification.

The work in three volumes, of which the last consists entirely of coloured plates, has an introduction containing notes on the mounting of mosquitoes, in which the author strongly urges the necessity of preserving specimens in 40 per cent. spirit for purposes of more complete identification. The first portion of the work is devoted to a short account of the external structure of the adult, pupal and larval conditions of the insects and of the bionomics of the different stages, and ends with a synoptic table of subfamilies and genera of the family of Culicidæ and a list of species of Culicidæ, and a further list arranged according to the countries in which the species occur.

The rest of the work deals with detailed descriptions of the members of the different genera. It is lavishly illustrated by many figures throughout the text, which serve to lighten very considerably the difficult task of identification. The coloured plates forming the third volume have been exceedingly well prepared, and their execution must have absorbed much time and labour. It is, however, much to be regretted that many of the drawings, in fact almost all those of insects collected in tropical countries, have been made from preserved specimens, and consequently do not reproduce at all exactly the colours of the insects in nature. It is well known how quickly their delicate colours fade after death and under the influence of the usually employed preservatives, so much so, indeed, that to investigators who are very familiar with the insects in their tropical surroundings the coloured representations in this work appear very untrue.

Without in any way wishing to detract from the great value of the portion of the book which details the specific characteristics of the numerous species described, it is to be regretted that the earlier portion, dealing chiefly with the bionomics of the Culicidæ, and for which the author has been largely dependent for his information on the authority of others who have studied the insects in the tropics, should occupy such a prominent position. In the short description of the parts of the proboscis of the mosquito, the author has shown himself unfamiliar with the minuter details of its structure. He advises the

disuse of the term "epipharynx," "as it is really part of the upper lip." This is not shown to be so if carefully prepared serial transverse sections are made of the proboscis. By this means it is seen that the epipharynx is a tunnel-shaped tube through which blood is drawn up and which is strengthened on each side by a chitinous rod, in the centre of which is a core of chitin-forming cells—prolongations forward of the cells lining the external chitin of the whole body. The epipharynx is by its dorsal surface very intimately connected with the "labrum," or upper lip proper, throughout its whole length. That the labrum does not, however, extend as far as the tip of the epipharynx is shown by the presence of the core of chitin cells which here approaches the dorsal surface. The two pieces, the labrum and the epipharynx, therefore represent two distinct organs, which are bound closely together for a great part of their length by a delicate connective tissue, so that the combined organ might rather be called the "labrum-epipharynx," a term first suggested by Dimmock. Near the base of the proboscis the labrum is composed of a curved lamella of chitin, concave upwards, convex towards the convex upper surface of the epipharynx—the open sides being closed by folds of delicate chitin, which unite below with the lateral rods of the epipharynx, the space thus enclosed being filled with delicate loose cellular connective tissue.

Mr. Theobald also describes the hypopharynx as "a small needle-like thread connected with a poison gland at its base." The hypopharynx does not lie between the four stylets (the mandibles and the maxillæ) and the epipharynx, but, as is well shown in well-prepared sections, the lower edges of the mandibles fit in between the hypopharynx and the epipharynx at the sides, and only in the middle line do the thin lower edges of the epipharynx and the upper surface of the hypopharynx meet. Moreover, the structure at the base of the hypopharynx is not a poison gland, but, a receptacle for the collection of veneno-saliva secreted by the salivary glands situated in the prothorax. This receptacle is somewhat trumpet-shaped, with sides of strong rigid chitin. The mouth opens on to the upper end of a groove which runs along the whole length of the hypopharynx, the veneno-salivary gutter; whilst the broad end is composed of delicate membranous tissue, and receives about its middle the insertion of the common salivary duct. Into this membrane also are inserted the tendons of delicate muscles. The receptacle is simply a store for saliva which is discharged by the falling back of the membrane, previously retracted by the muscles attached to it.

Mr. Theobald emphasises the importance of the scale structure of the insects, and considers it to be one of the most important characters for both generic and specific distinction; the whole classification in the monograph is mainly based on the scale structure. In the description of the wings, the terminology of Skuse, which is the simplest and best suited for purposes of identification, has been adopted.

The paragraphs on the bionomics of mosquitoes treat chiefly with the habits of Anopheles and Culex. These paragraphs contain many incorrect and misleading statements, and other recent works might be consulted for more trustworthy information on this subject. For example, the author concludes that *Anopheles maculipennis* does not bite here in England, and suggests the question whether this may not have some bearing on the dying out of malarial fever in this country. Now there is no doubt that *A. maculipennis* have been found gorged with blood in some parts of England in bedrooms and other places. Moreover, however closely the distribution map of the English Anopheles corresponds with the old malarial district map which Dr. Nuttall has worked out, it is quite certain that there is hardly any district of England entirely free from Anopheles, which are easy to find if diligent search be made.

He further states, on the authority of Dr. Daniells, that in the greater part of India blackwater fever is unknown; on the contrary, however, this disease is more prevalent in some parts of India than in Africa.

In that greater portion of the work which deals with the classification and descriptions of the mosquitoes, the author has prepared extremely serviceable and minutely detailed entomological accounts of the characteristics of all the then known species. Of the old genera, the following have been retained:—Culex, Anopheles, Ædes, Mochlonyx, Megarhinus, Psorophora, Sabethes, Corethra, Uranotænia, Hæmagogus and Tæniorhynchus (modified). The new genera added by Mr. Theobald are Wyeomyia, Deinocerites, Ædeomyia, Panoplites, Eretmapodites, Janthinosoma, Stegomyia, Mucidus, Toxorhynchites and Trichoprosopon.

Of the 300 species described, 136 are new. The majority of species described are those found in and around towns or are known pests to travellers and traders; a few, of the genera Megarhinus and Sabethes, which probably occur more abundantly in forests, are also described.

The author deserves very great credit for the enormous amount of work which must have been entailed in the preparation of the details of this large number of species, and it is extremely desirable that in its second edition the great value of the work, especially to those who are engaged in the study of disease in tropical and subtropical countries, will be still further increased by the correction of the errors and contradictions which have evidently been overlooked in the hurry of publication.

THE DIRECT-CURRENT ARC.

The Electric Arc. By Hertha Ayrton, M.I.E.E. Pp. xxv + 479. (London: The *Electrician* Printing and Publishing Company, Ltd.) Price 12*s*. 6*d*.

THERE are few electrical phenomena which are of more interest than those exhibited by the electric arc, or which are more difficult to investigate. The complexity of the laws by which it is governed and the number of factors which can be varied independently make any research into its properties of a laborious character. Mrs. Ayrton is to be congratulated, not only on the painstaking investigations which she has carried out on the direct-current arc, but also on the remarkable success which has attended her work. Much of the book before us is already familiar as the result of papers

published in the *Electrician* or communicated to scientific societies. But in one sense the book may be said to be entirely new, as it presents for the first time the results of Mrs. Ayrton's work in the form of a connected whole in which the interdependence of the various parts is made manifest.

After a short chapter on the general appearance of the arc, Mrs. Ayrton gives, in a chapter of nearly eighty pages, a history of its discovery and development and of the investigations to which it has been subjected. Though the discovery is usually attributed to Davy, it is clear from the quotations given by Mrs. Ayrton that the arc was evolved from the electric spark without any distinct recognition of the difference between the two; to Davy, however, belongs the credit of the first description of an undoubted arc, from which dates, probably, its recognition as a distinct phenomenon. The remainder of the chapter, in which all the important papers on the arc are considered, is of great value, especially, perhaps, to the student, as it leads by easy gradation from the simpler theories which were advanced at first to the more complex and complete explanations which have to be put forward now that all the problems arising are more fully realised.

Mrs. Ayrton then passes on to the behaviour of the arc immediately after striking, and to the necessity of working with "normal" arcs, that is, arcs in which the P.D. has assumed its steady value for the given current and length of arc. The laws that govern the P.D., current and other electrical quantities are then considered in detail, as a result of which Mrs. Ayrton's now familiar equation connecting the P.D. with the current and length of arc is derived. The equation, which is of the form $V = a + bl + \frac{c + dl}{A}$, where a, b, c and d are constants depending on the carbons and V, l and A the P.D., length of arc and current respectively, is shown to fit in with the results of the experiments of previous investigators, even though the equations which they had themselves advanced were different or less complete. This equation, which applies only to solid carbons, is very accurate over the range studied by Mrs. Ayrton. The effect of cores in cored carbons is considered, and it is shown, by an examination of the P.D. between the carbons and the arc, how the various terms of the equation can be correlated with the physical phenomena in the arc.

Especial interest attaches to the above equation on account of its connection with the theory advanced in the final chapter. But apart from this, the whole of this portion of the work is of the highest intrinsic value. We cannot, with the space at our disposal, consider it in any detail, but we might particularly draw attention to chapter viii., which deals with the stability of the arc, and to chapter x., on hissing arcs. The chapters dealing with the efficiency of the arc, considered first as a consumer of power and secondly as a source of light, should appeal strongly to those who are interested in arcs from the practical standpoint, especially as they show how much the commercial standard falls below that actually obtainable. The arc enjoys at present the distinction of being the cheapest form of artificial light, so that the only competition to be met is that between different forms of lamps; but this is quite sufficient to lead to the advisability of an attempt at improvement by the scientific study of the best conditions of working.

In chapter xii., Mrs. Ayrton puts forward her theory of the arc. It is hardly fair to consider this theory apart from the rest of the book, as it arises naturally out of the views advanced therein. For a long time experimenters have been divided into two camps, those who believed in the existence of a back E.M.F. in the arc and those who did not. According to Mrs. Ayrton's view, it is not necessary to assume the existence of a back E.M.F. to account for the high fall of potential between the positive carbon and the arc, as it can be explained in another way. The conducting part of the arc consists, on this view, of a very thin film of true carbon vapour at the crater and of carbon mist throughout the rest of the arc. The very high specific resistance of the carbon vapour accounts, not only for the fall of P.D., but also for the volatilisation and cratering of the positive carbon. It is shown from actual measurements of the cross-sections of the mist and vapour that their variation with current and length of arc lead to a law of variation of P.D. precisely similar to that given in the above equation. If we may venture criticism, we should like to point out that the explanation suffers from being only qualitative, and though the form of the equation is the same there is nothing to show that the constants are of the same magnitude. It remains to be shown by experiment whether this is the case or not.

The method of measuring the "true" resistance of the arc by a superimposed alternating current fails, as Mrs. Ayrton shows, unless it can be proved that the added current in no way affects either the resistance or the back E.M.F. (if existent). It is well known that this method leads in some cases to negative results, and Mrs. Ayrton points out that it may lead to any value from a large negative one to that of the "true" resistance, according to the frequency of the added current, which must be as high as "many thousands of alternations per second for the resistance of the arc not to be altered by it." In a recent paper by Mr. Duddell, read before the Royal Society, the results of experiments with a frequency as high as 120,000 alternations per second were given, and the author claimed that they showed a true resistance of about four ohms and a back E.M.F. of twelve volts. Unfortunately, this paper was not published at the time of the completion of Mrs. Ayrton's book, but it would be interesting to learn whether she can harmonise it with her theory. Incidentally, it may be noted that Mrs. Ayrton's explanation accounts for the effects produced by cores and for the shapes to which the carbons burn, and there can be little doubt that, whether or not it proves sufficient to rank as a complete theory, it is a great advance towards the clear appreciation and the solution of the problems presented.

In conclusion, we may commend the excellent drawings of arcs and carbons with which, in addition to curves and diagrams, the book is copiously illustrated. Altogether the book deserves to rank as one of the most important contributions to electrical literature that has appeared of late years.

M. S.

OUR BOOK SHELF.

Palaeontologie und Descendenzlehre. By E. Koken. Pp. 33; illustrated. (Jena: G. Fischer, 1902.)

IN this essay, read before the Congress of Science and Art held at Hamburg in September last, the author briefly explains in a popular manner some of the more important evidence in favour of evolution afforded by palæontological researches and discoveries. After alluding to the old belief in the separate creation and immutability of species, Dr. Koken mentions Lamarck's theory, and then passes on to the revolution in scientific thought and belief brought about by Darwin's work. With a brief reference to Waagen's investigations and theories in regard to the mutations of ammonites, and the expression of the belief that what holds good in this case will also apply to other groups, he proceeds to cite some of the most striking instances of the descent of one group from another. In regard to mammals, it is considered that the earliest forms were nearly allied to the Insectivora, and that from these were developed the Creodont Carnivora, from which subsequently branched off the placentals on the one hand and the marsupials on the other. Allusion is next made to the importance of Archæopteryx, as in some respects a connecting link between birds and reptiles. Attention is then called to the important evidence which has been obtained during the last few years as to the relationship between the anomodont reptiles and mammals on the one hand, and between the former and the labyrinthodont amphibians on the other. A wide cleft still, however, separates amphibians from fishes—a cleft which, in the author's opinion, is in no wise spanned by the lung-fishes, the amphibian resemblances of which he believes to be largely adaptive.

Having cited the foregoing and other instances of genetic relationship between various classes, Dr. Koken next proceeds to consider numerous cases of intergradation between minor groups. In the Mammalia he first of all refers to the now well-known fact that in the early Eocene it is almost impossible to distinguish between unguiculates and ungulates, and then proceeds to discuss several of the phylogenetic lines into which the latter have developed. Special mention is made of the clawed chalicotheroids of the Miocene and Pliocene, as a remarkable side-branch of ungulate development; and Kowalevsky's doctrine of the "adaptive" and "inadaptive" modifications of the artiodactyle carpus is fully explained. A very remarkable instance of the evolution of one type from another, which has not received so much attention as it deserves, is exemplified among the dinosaurian reptiles by the Liassic *Scelidosaurus* and the Upper Jurassic *Stegosaurus*, skeletons of which are figured in juxtaposition.

This excellent little sketch concludes with some remarks upon former land connections and general observations on the evolution of the surface of the globe and its inhabitants. R. L.

The Laboratory Companion to Fats and Oils Industries By Dr. J. Lewkowitsch, M.A., F.I.C. Pp. xi + 147. (London: Macmillan and Co., Ltd., 1901.) Price 6*s*. net.

THE book is essentially a collection of tables of the numerical values obtained in the analysis of oils and fats, and of tables useful in industries where oils and fats are employed; it forms a companion to the author's earlier publication on the "Chemical Analysis of Oils, Fats and Waxes." The amount of information in the book is very extensive, as may be judged from the fact that the number of oils only, for which constants are given is 111, and the number of fats 65.

The author states in his preface that "numerical values, so-called constants, and variables, have been carefully scrutinised, and only the most reliable ones have been given. In some cases the most probable values had to be decided on." As the consequence of this, we find in the majority of cases single numbers given for the iodine value, saponification value, &c., of oils and fats. This precludes reference to the results of the various observers. The arrangement of materials under the heading of separate manufactures is a very useful feature. Thus, under the heading "soap manufacture," are eight tables, including such information as the percentages of caustic soda and caustic potash in caustic lyes, the influence of temperature on the specific gravities of caustic soda solutions, and the amounts of caustic alkali solutions required to saponify fats of certain mean molecular weights.

Colour-variation in the Guinea-fowl.

As this bird is such a recent addition to the poultry-yard (for, although known to the Romans, it went out of domestication in the Middle Ages) and has not been selectively bred by fanciers, its spontaneous variations are particularly interesting. Here, in India, where guinea-fowls are much bred, several well-defined types of coloration constantly present themselves in these birds, kept solely for the table.

There is first the normal dark-grey form, speckled with white and with white bars on the primary quills. This is the commonest; but it varies from the wild type in having more white on the naked head and neck, and generally in having the toes and shanks more or less orange instead of black.

Secondly, there is a form, marked exactly as the above, but on a lavender or French-grey background; it resembles, however, the dark normal bird in the coloration of the head and legs.

A third form is of a purplish-slate without spots, but retaining the white bars on the primary quills; the head and legs also are coloured as in the common normal form.

There are also, of course, albino birds, which have entirely orange-yellow legs and feet, and no dark purplish hue about the bare head, but only white and red.

The pied birds which occur are particularly interesting, the marking being very constant—white underparts and white primary quills. The white may invade more of the wing, and may be reduced in amount on the breast and wings until the coloured form is reached, but I have never seen a splashed or blotched bird, such as one often finds among pigeons or ducks.

All the colours, spotted-grey, spotted-lavender and slate, may be pied like this, but the normal spotted-grey oftenest, as one would naturally expect from its greater frequency. The bare dewlap of these pied birds is white when the white feathering comes as far, not blue or purple as in coloured birds.

The only unspotted-lavender bird I have seen as yet was a white-pied one.

I have not had the same opportunities of studying guinea-fowls in England as I have out here, but certainly, to the best of my recollection, all the colour-types I have described occur there, which, considering the difference of climate, shows that this factor does not determine variation in this bird.

As I have remarked above, the pied birds grade into the coloured ones; but typical specimens are more common than intermediate ones, and there is no gradation whatever between the two spotted forms, the dark-grey and lavender. The unspotted slate form does often display a few white-marked body-feathers, but by no means tends to intergrade with the normal type.

If this bird, with its uniform body-colour and barred primaries, occurred in a wild state, the markings of the quills, concealed as these are in repose, would be set down to sexual selection or claimed as "recognition marks"; and a similar cause would be

invoked to account for the white underparts and white quills of the pied forms, which would be well concealed if the bird lay flat on the ground.

Yet in this case of a bird which has been protected by man for a few centuries only, we see these beautifully arranged markings appearing suddenly and almost in full perfection, by simple variation happening to take, in this species, these definite forms.

Last winter I procured in the Bazaar here a pintail snipe (*Gallinago stenura*), marked much like a pied guinea-fowl, with white outer primaries, some white down the breast, and orange toes. This is the kind of resemblance which is put down to mimicry when occurring between two wild *species* of similar size inhabiting the same country.

And thus the view of Darwin, that mimicry has always commenced between forms with a considerable resemblance to start with, receives confirmation; as also from the fact that, in birds at any rate, so many cases of "false mimicry" between species inhabiting distant countries can be shown to occur.

At any rate, whether we are dealing with recognition-marks, sexual selection or mimicry, it seems to me that the study of variation constantly tends to show that natural selection has always at hand far greater material in the shape of colour-variation than is commonly supposed. F. FINN.

Indian Museum, Calcutta, May 1.

A Cubic and Submerged Cubes.

THE following is a curious puzzle. Given a square box having an area of 27 square inches on its floor and having vertical sides, and filled with water to a depth of 2 inches, it is required to find the size of a heavy cube which, when resting on the bottom of the box, will have its upper surface high and dry above the surface of the water. The curious thing is that there is no such cube. A very small cube will have its top nearly 2 inches below the surface; the largest cube that can go into the box, its edge being 5 inches and a fraction, forces all the water above it except a film and, again, has its top nearly 2 inches below the surface. There is one cube, that with its edge 3 inches, which has its top just on a level with the surface of the water; its top may be dry, but is not both high and dry. All other cubes are more or less submerged. This is a numerical example of a unique case.

For an example of the general case, let the area of the floor of the box be 28 square inches and let it contain 48 cubic inches of water. Now it will be found that there are two cubes which, when placed on the bottom, have their tops on a level with the surface of the water. They are the cubes with edges 2 inches and 4 inches respectively. All cubes between those two have their tops high and dry above the surface, while all other cubes are more or less submerged.

It may be interesting to know that these cubes give a physical interpretation to the roots of the cubic obtained by equating the trinomial x^3-ax+v to zero. The equation has two positive roots, m and n, and a negative root, $(m+n)$. If a be the area of the bottom of the box and v the volume of the water, then x is the edge of the cube which has its top flush with the surface of the water. There are, therefore, in general two such cubes, m^3 and n^3, the negative root being inadmissible. Since $a=m^2+mn+n^2$ and $v=mn(m+n)$, by giving values as $m=4$ and $n=2$ we obtain $a=28$ and $v=48$, as in the second numerical example above. Again, if we suppose the two positive roots equal, as $m=n=3$, we have $a=27$ and $v=54$, as in the first example.

If a value be assigned to x lying between m and n, it is readily shown that the trinomial is no longer zero, but is negative, which is the condition that the top of the cube shall stand above the surface, while for values of x on either side of m and n the trinomial becomes positive, so that these cubes are submerged. THOS. ALEXANDER.

The Electrical Resistance of the Blood.

IN a letter published in NATURE of July 13, 1899, the author communicated some of the results he had obtained in measuring the electrical resistance of the blood. These results showed that the average resistance of normal blood at 60° F. measured by Kohlrausch's method in the apparatus used amounted to 550 ohms, while the specific resistance was 93·5 ohms. Further, a marked change was observed in pernicious anæmia, the resistance in this disease falling to about one-half (300 ohms) that of normal blood. The author has shown (*Proceedings* of the Royal Society of Edinburgh, December 21, 1891) that the electrical resistance of the urine in this disease is greatly increased (about 100 ohms specific resistance instead of the normal 45 ohms); hence we have the striking fact that, while the urine contains too few salts, the blood contains an abnormal amount. The kidneys, then, must obviously be in fault. In a patient, aged fifty-one, suffering from pernicious anæmia, under the care of Dr. A. James, in the Edinburgh Royal Infirmary, the blood resistance, measured on February 25, 1902, amounted to 300 instead of to the normal 550 ohms. The resistance of the urine, measured at the same time, amounted to 88 ohms instead of to the normal 45 ohms. The blood corpuscles numbered 900,000. The blood resistance in diabetes mellitus is high, like that of the urine. A number of experiments have been made by me to ascertain the time occupied by ingested sodium chloride to reach the blood. The blood resistance in five cases was measured before taking 30 grains of the salt and at five-minute intervals afterwards. The average time taken for the first lowering of the resistance of the blood was 15·4 minutes, and the maximum effect was produced in 21·4 minutes.

Further observations on these lines promise interesting results. DAWSON TURNER.

Chickens Hatched in a Tree.

YOU may, perhaps, think the following account of an incident which happened here last week in our poultry-run worth printing.

About May 1, one of our hens, which was known to be laying, totally disappeared. For some ten days she baffled all our efforts to discover any traces of her. At last she was found sitting on the eggs she had laid in a squirrel's nest, in a Scotch fir-tree, at a height of 16 feet from the ground.

For the remaining eleven days of her incubation the hen was watched descending, and ascending from bough to bough to her high perch, at first every day once, but latterly once every other day, as far as could be observed.

On Thursday, May 22, the hen was found with six live chickens and two dead ones at the foot of the tree. Unluckily no one witnessed the actual descent. She could not, however, be persuaded to enter an ordinary hen-coop.

With some trouble, the hen and her six chickens were got eventually on to some straw in an old railway-carriage, which I had erected some years ago on the edge of the hen-run, which is sheltered from the north wind by a fir-plantation, where many squirrels build their nests.

In order to convey her chickens from the railway-carriage to the ground, the hen was seen to spread out her tail and descend with all six young chickens at once on her back. Doubtless she had conveyed them down the 16 feet from the fir-tree in the same fashion, but probably only one or two at a time.

Six-Mile-Bottom, Cambs., May 25. W. H. HALL.

A Curious Optical Effect.

A FORTNIGHT ago, while standing with my back to the sun, which for a few minutes happened to be shining brightly, and with my face within a few inches of some darkly painted boards, which were covered with minute sparkling particles, presumably from an adjacent coke-grinding machine, I noticed that on approaching my face a little closer, the particles became iridescent and apparently magnified to a size of about one-eighth of an inch. On closing one eye and looking closer, concentric circles appeared, with a cross × over them, and in some cases there was a smaller circle just touching the inner margin of the larger one; in others the small circle seemed to be nearer the centre of the larger one. On a subsequent examination, when the sun was not so bright, the concentric circles seemed to be wavy and indistinct, as was also the case with the cross. The whole thing reminded me of illustrations I have seen of effects produced by tourmalines under certain conditions.

If this is a commonly observed phenomenon, I should feel obliged for any references to literature on the subject.

THE PROPOSED EXPERIMENTAL TANK FOR TESTING SHIP MODELS FOR RESISTANCE.

THE recent opening of the National Physical Laboratory, as described in NATURE on March 27, marked an epoch in the advance of science into the commercial development of this country. Equipped as the Laboratory will be with the best appliances for testing materials and instruments of precision, for fixing standards of measurement and comparison, it will supply that which, in other countries, has already been recognised as a vital necessity to national commercial prosperity.

There is, however, a branch of scientific investigation not contemplated in the original scheme for the Physical Laboratory and which it is now proposed to include in it, namely, an experimental tank for testing, by means of models, the resistance of vessels either already in existence or only in the stage of design.

The system followed in the practical application of theory to the solution of these problems of naval architecture was devised by the late Mr. Wm. Froude. In his first experimental tank, erected at Torquay more than thirty years ago, Mr. Froude carried out the researches which led to his well-known discovery of the laws which govern the resistance offered by water to the propulsion of ships.

Although the method pursued has often been described in NATURE and elsewhere, a brief outline of it, by way of reminder to our readers, may not be out of place.

A model of the vessel the resistance of which is to be tested is made either of wood or, preferably, of paraffin. If the latter material is used, the block is cast roughly to the shape of the proposed hull and then placed in a cutting machine, where it is planed down to the exact shape required, by a cutting tool, the movements of which are controlled by the operator. The latter guides the instrument by following with a pointer the lines of the hull on a drawing, the connection between the pointer and the cutting tool being so exact that the contour lines of the design are faithfully reproduced on the hull of the model. The final touches are done by hand, and the trim of the model, when placed in the water, serves as a check on the accuracy of the workmanship.

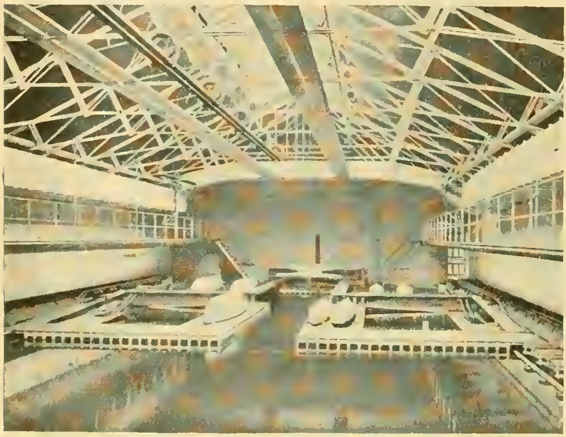

FIG. 1.—View of Washington Tank, north end, showing Wave Breaker.

The model, when ready for testing, is placed in the tank and attached to a travelling framework or "carriage" which spans the width of the tank and is propelled either by a self-contained motor or by a stationary engine and cable. The travelling carriage is fitted with a dynamometer and registering apparatus, which records automatically the pull or resistance of the model and the speed at every point of the course traversed. Thus, at the conclusion of a series of trial runs at different speeds, accurate diagrams are obtained, from which the curves of resistance can be plotted for the various speeds considered, and, by interpolation, for any intermediate speed. In a similar way, the effect of alteration of trim and displacement can be easily determined, and the most interesting and useful experiments on the effect of alterations to existing vessels, on the efficiency of various forms of screw propellers, on the relative oscillations of different types of hull, and many other problems that are met with in naval architecture can be carried out with results that approximate closely enough for all practical requirements to those actually obtained on full-sized ships. The economy in using models instead of full-sized vessels for obtaining such experimental data is sufficiently obvious, and need not be insisted upon.

It is to Mr. Froude also that we are indebted for establishing the exact relations that subsist between the model and the full-sized vessel, upon which depends the success of the experimental method. This relation or law of "corresponding speeds" is to the effect that, comparing ship and model, "the resistance is in proportion to the cube of the linear dimension at speeds proportional to the square root of the linear dimension."

The practical value of Mr. Froude's labours was recognised by the Government at an early period, and his tank at Torquay was established under Admiralty supervision in 1870. Fifteen years later, the Government decided to build and equip a much larger tank at Haslar, near Portsmouth, where models 14 feet long could be run over a course of 400 feet. This tank is under the direction of Mr. R. E. Froude, whose valuable researches by means of model experiments have greatly added to our knowledge of the laws relating to fluid resistance, oscillation of ships, propeller efficiency, and other problems of naval architecture.

The tank at Haslar, erected at Government expense, has been devoted purely to Admiralty work, and it is not found possible to extend its use to the testing of models for private shipbuilders.

The only other tank of this kind in the kingdom is that constructed by Messrs. Denny at Dumbarton, and this is only employed upon the work of that firm.

Recognising the need for a tank where private shipbuilders could at any time send a model to be tested, the Institution of Naval Architects, at their summer meeting in Glasgow last year, passed a resolution to the effect that such a tank ought to be established, and the council of that Institution has since been considering how this proposal could best be carried out.

The two chief difficulties were the selection of a site suitable for the purpose and the raising of the necessary funds to carry the scheme out. As regards the latter requirement, it was felt that those interested in the welfare of the shipowning and shipbuilding interests of

the country would not be slow to guarantee the necessary funds, provided a site could be found easily accessible, and where a tank could be placed under independent, competent and impartial control.

In the grounds of the National Physical Laboratory at Bushy House, a site has been selected which it is proposed to devote to the purpose. This situation, besides being very convenient as regards the nature of the ground (to quote from Lord Glasgow's recent presidential address), offers "many important advantages; a position conveniently near the metropolis, the proximity of an established power installation and a highly trained technical staff, and, above all, a board of management of the highest standing, entirely unconnected with any individual commercial enterprise, whose control would in itself guarantee the treatment in strictest confidence and impartiality of all questions submitted to them."

It is hoped, therefore, that shipbuilders and shipowners and others will come forward liberally to form the necessary guarantee fund for the construction and equipment of the tank, which together are estimated to cost about 15,000*l*. The scheme, which has received the hearty support of His Royal Highness the Prince of Wales, is now ripe for carrying into execution, and it is felt that no more time should be lost in adding this necessary auxiliary to the equipment of British shipyards. The Prince of Wales, in opening the Laboratory on March 19, expressed his confidence—a confidence which we feel sure will be justified by results—that "through the generosity of the public, the necessary means will be forthcoming to meet these difficulties and to secure that which is almost an essential to the shipbuilding industry of a country possessing the largest mercantile marine in the world."

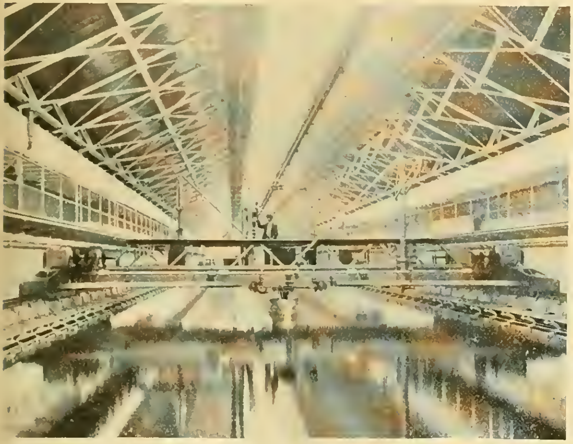

FIG. 2.—View of Carriage and Model at rest.

Other countries have not been slow to realise the value of model experiments; Italy has her experimental tank at Spezia; Russia one at St. Petersburg; Germany, besides having a private tank at Bremerhaven belonging to the Norddeutscher Lloyd, is about to erect one in Berlin; and the United States of America, not to be outdone by the old countries, has built the largest tank of all at Washington, where 20-feet models are tested over a 470-feet length of run.

All these tanks, excepting that at Bremerhaven, are worked by Admiralty staffs of their respective Governments, but the private shipbuilder has not been forgotten, and in each case he may, subject to certain regulations and to the payment of fees sufficient to cover the cost of the experiments, make free use of the tank for carrying out researches of his own. But, however convenient it may be to have a tank erected at the expense of a paternal Government, it can hardly be doubted that the arrangement has its drawbacks; private individuals would, at times of pressure, have to give way to Government needs, and at all times the results of the experiments are of necessity obtained as much for the benefit of the Admiralty as for that of the private individual. Both these drawbacks are obviated by placing the management of the tank in private, but disinterested, hands.

Some views of the Washington tank are reproduced here from a paper by Mr. D. W. Taylor (naval constructor, U.S.N.), read before the American Society of Naval Architects and Marine Engineers, and they give a good idea of its chief features of interest. The "carriage," which draws the model through the water and contains the recording apparatus, spans the entire width of the tank (46 feet 6 inches) and weighs nearly thirty-two tons. It is propelled by four electric motors, shown in Fig. 2 at

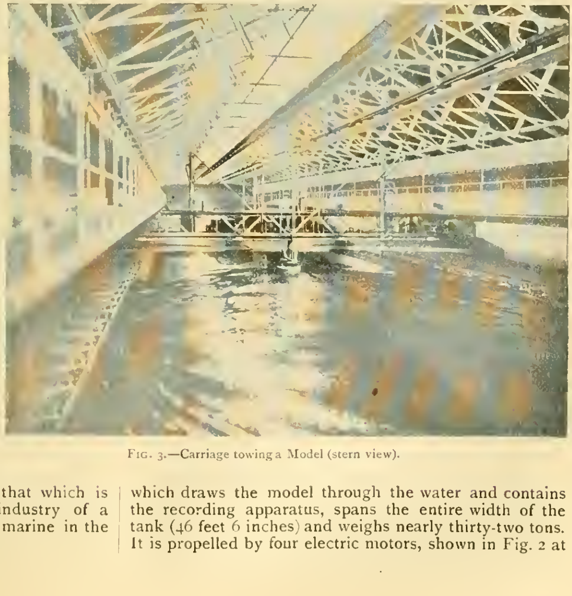

FIG. 3.—Carriage towing a Model (stern view).

the extreme ends of the framework. As the speed attainable is upwards of 20 knots—developed in a 200 feet run—powerful emergency brakes actuated by hydraulic pressure are provided, in addition to the ordinary friction brakes, and the whole carriage is under perfect control for stopping and starting, and maintaining constant speed during a run.

The extreme length of water surface in the Washington tank is 470 feet, of which about 370 is of the full section across, the remainder being the narrow extremities available for starting and stopping. In order to reduce the time lost between runs through waiting to obtain still water, side troughs 12 inches square in section are laid throughout the length of the tank to absorb the wave disturbance caused by a model run, while at the north end of the tank (Fig. 1) a series of wooden strips placed vertically act as a wave breaker at the close of the run.

Great care is taken to ensure the purity of the water by treating it with alum and filtering through sand

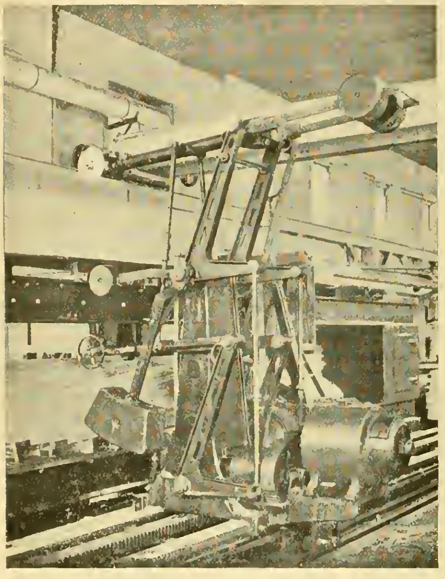

FIG. 4.—Model Shaping Machine.

before admission to the tank. The capacity of the latter is about one million gallons, and the tank can be pumped dry when required in about four hours by a 12-inch centrifugal pump. The temperature in the building is kept as far as possible uniform and slightly above that of an ordinary living room.

A special feature at the Washington establishment is the employment of wood for the models instead of paraffin. This is on account of the heat in summer being too great to allow of the latter material being used, preferable though it is in other respects; for the cost of wood is higher, the difficulties of shaping it to the specified lines are greater, more time is required, and it is, of course, impossible to reduce it to bulk after use, as in the case of paraffin. On the other hand, a wooden model is less liable to accidental damage and retains its shape better if required for future use.

Fig. 3 shows a model being towed through the water, the wave formation being clearly visible; Fig. 4 gives a view of the shaping machine at work on a model.

R. W. D.

VOLCANIC DUST FROM THE WEST INDIES.

IT was mentioned last week that the West Indian mails had brought packets of volcanic dust which fell at Barbados and elsewhere to several institutions and investigators in this country. The characteristics of this material have been minutely examined, and the following descriptions of them will be found of interest.

I.

At the meeting of the Geological Society on Wednesday, May 28, Dr. Flett communicated a preliminary note on the ash which fell at Barbados. The specimens had been forwarded by Dr. Morris, of the Imperial Department of Agriculture, to Prof. Judd, who placed them in the hands of Dr. Flett for examination. The ash consists principally of plagioclase felspar allied to labradorite, hypersthene, monoclinic augite and magnetite. The crystals are often perfectly idiomorphic, and it may be safely inferred that they were formed in the magma before the actual eruption took place, and blown into the air along with the molten material by the force of the escaping gases. A small amount of glass containing steam holes is adherent to some of the crystals, but many are perfectly clean.

The crystals are similar in every respect to the phenocrysts of hypersthene-augite-andesite, a type of rock well known among the recent volcanoes of the Pacific region. In the discussion which followed the reading of Dr. Flett's paper, it was pointed out by Mr. Prior that the same type of rock occurs in other West Indian islands, and also in the Mexican volcanoes, so that the petrographical evidence serves to connect the West Indian volcanic region with the Pacific rather than with the Atlantic. An analysis of the ash by Dr. Pollard was communicated by Dr. Flett. It is quoted below.

SiO_2 ...	52·81	MgO ...	5·19
TiO_2 ...	·95	K_2O ...	·60
Al_2O_3 ...	18·79	Na_2O ...	3·23
Fe_2O_3 ...	3·28	P_2O_5 ...	·15
FeO ...	4·58	SO_3 ...	·33
MnO ...	·28	Cl ...	·14
(CoNi)O ...	·07	H_2O 105° ...	·20
CaO ...	9·58	H_2O above 105° ...	·17
		Total ...	100·35

It must be remembered that this analysis does not represent the composition of the material as it existed in the subterranean reservoir immediately before the eruption, but rather the bulk analysis of the crystals which had separated out, together with only a small admixture of the glass.

If this glass could be separated and analysed it would probably be found to differ from the bulk analysis of the crystals in the same way as the glassy base of hypersthene andesites differs from the bulk analysis of the phenocrysts; that is, it would contain more silica, less lime, iron and magnesia, and more alkalis, especially potash. In Old Red Sandstone times the volcanoes of the Cheviot district erupted hypersthene-andesites, and the glassy base of one of these rocks was analysed by Dr. Petersen with the following result:—

SiO_2 ...	66·25	MgO ...	·28
Al_2O_3 ...	13·59	K_2O ...	4·95
Fe_2O_3 ...	3·11	Na_2O ...	2·25
CaO ...	2·75	H_2O ...	5·89
		Total ...	99·07

The samples of ash from Barbados hitherto examined consist mainly of the crystals. The glassy matter which represents the mother liquor appears to have been vanned away and deposited elsewhere. This, if it should turn out to be the case, is somewhat unfortunate, for the glass, with its higher percentage of potash, would have been more useful as a fertilising agent.

J. J. H. TEALL.

II.

The photographs here reproduced are those of the volcanic dust which fell in Barbados on Wednesday, May 7. The circumstances attending the fall have been so graphically described in a letter, dated May 10, from Mr. G. C. Edghill, the manager of the sugar plantation on which the dust fell, to its owner, Captain Forte, that it seems best to quote parts of the letter *verbatim*. It is to the kindness of Captain Forte (a friend of my father's) that I owe both the letter and the specimen of the dust.

Mr. Edghill writes as follows :—

"Wednesday morning, May 7, opened normally, the day being fine and a steady breeze blowing. Soon after mid-day we began to hear deep subterranean explosions, increasing in intensity, some single, others in volleys of about five or six. Some of these made the earth vibrate like a slight shock of earthquake, and they continued for two or three hours. Then a black cloud began to rise in the direction of St. Vincent, which rose and spread towards and around us, *although the wind was blowing from us towards it*. (The italics are mine.)

"About four o'clock the edge of this cloud began to obscure the edge of the sun, and dust began to fall, at first lightly, but increasing gradually in volume, and making a noise like a fine drizzle. Rapidly then the light grew dim, and the appearances were like those of a total eclipse of the sun, but very grand and startling—making one feel creepy. At five o'clock it was quite dark, and our mill hands had to be lent a lantern to see their way home. At six o'clock it was as dark as midnight, and we went to bed as usual, the only disturbance in the night being incessant thunder and lightning in the direction of the mountain. . . . When the daylight came it was alarming to see everything covered by a layer of dust a quarter of an inch thick. I say a quarter of an inch, because I put out a dinner plate on the lawn above the house when the fall began, and the next morning the dust lay a quarter of an inch thick on it. All the green had given place to a light brown, and the canes had almost quite disappeared. . . . I forgot to mention that the dust was cool and smelling strongly of brimstone. It is estimated that upwards of fifteen tons per acre fell on the island. . . ."

FIG. 1.

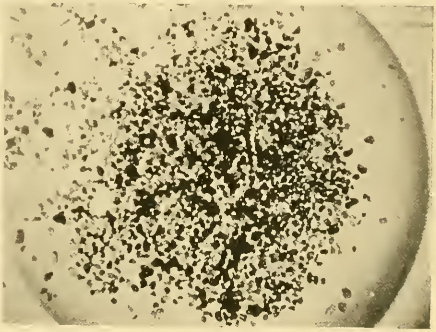

FIG. 2.

To turn to the two photographs, which show the dust magnified exactly seven and a half diameters (or about 56 times in area). Fig. 2 is precisely the same view of the same dust particles as those seen in Fig. 1, except that the light comes through them in Fig. 2 whereas it is shining down upon them in Fig. 1. In other words, Fig. 1 is by reflected light, but Fig. 2 by transmitted light ; Fig. 2 therefore shows clearly which particles of the dust are transparent and which opaque ; and it is very instructive carefully to compare Figs. 1 and 2. It will be seen at once what a very large proportion of the particles are transparent—more than two-thirds, in fact. Most of the opaque particles are very strongly magnetic, and are certainly magnetic oxide of iron (they are not titaniferous iron, still less hæmatite). But these are mixed with others, also attracted by the magnet, but far less so, apparently of a dark-coloured mica. The mean size of these dark particles is about 0·008 cubic millimetre. When thrown into water, about half the powder sinks at once, and if the floating particles be examined with a high power, it will be seen that they are all buoyed up by air bubbles ; on violently agitating the dust with the water, the dust sinks, so that it does not seem to contain any of the *lighter* kinds of pumice, which through their extremely porous nature cannot be made to sink so easily.

When the dust is thrown into a solution of density 2·52 (a solution of mercuric iodide in potassium iodide), about one-fifth of its particles float ; these are larger and lighter in colour than the rest, and under the microscope have the appearance of a yellowish-brown semi-transparent glassy material, with bubbles in it, and numerous fine air tubes running through its substance all more or less in one direction ; moreover, it shows evident signs of fusion on its surface, and is no doubt a rather heavy kind of pumice ; along with these particles are some of a clear greenish glass, full of cavities *which do not act on polarised light*—they are transparent obsidian or true volcanic glass. Of the particles which sink in the double iodide solution, those of black, metallic-looking magnetite have already been mentioned, and also the dark-coloured mica ; with these there are remarkably perfect crystals of a felspar, some of which contain cavities of a regular geometrical shape. These crystals have curiously retained in many instances the primitive sharpness of their edges. Probably a sodium felspar is present, as well as the potassium compound, for the ash, after digestion with pure ammonium fluoride, leaves a residue giving a brilliant and long-lasting yellow colour to a Bunsen flame, and with a spectroscope, the lines of potassium and calcium are brilliantly shown as well as the double sodium line. There are also in the ash a considerable number of splintered crystals, of conchoidal fracture, and hard enough to scratch glass, which, like all the crystals present in this ash, act powerfully on polarised light ; they are quartz, and the edges of most of these particles are blunt and the corners visibly rounded. There are also a large number of transparent crystals of a brownish-green colour, very well preserved in form, which a rather hasty examination would indicate as olivine, but of this I do not feel quite sure. The residue after the ammonium fluoride treatment proved to consist chiefly of compounds of iron, calcium and magnesium ; there is a trace of some metal present which forms a sulphide insoluble in hydrochloric acid, but what it is I could not determine, the total quantity of ash at my disposal being only 1·304 grams. Perhaps it is copper—whatever it may be, it is only present in very minute quantity. Magnesium is present in considerable quantity, almost certainly as a silicate. There is more than a trace of manganese, and aluminium is also present, but only in very small amount. Barium and strontium compounds are absent. The dust, when heated carefully in a hard glass tube, gives off a trace of water, which it appears to hold mechanically, and afterwards yields a slight crystalline sublimate, probably of some ammonium compound (? the chloride). No sulphur could be certainly detected, in spite of the strong sulphurous smell which, it seems from the account, the dust had

when it fell, and which points to the ashes having been accompanied by an invisible cloud of sulphur dioxide on their emission from the crater, so that they mechanically occluded some of the gas. The ash gave no effervescence with a powerful acid, the action of the acid being closely watched under the microscope,[1] so that carbonates, such as limestone, and ammonium carbonate seem entirely absent. Finally, the drift of the ash against the wind will have been already noticed. This was due, one would naturally suppose, to the existence of a contrary upper current of air into which the ashes were projected, as they were, indeed, in the great eruption of 1812, when, in spite of the N.E. wind blowing strongly at the time, the ashes fell on the Azores, some hundreds of miles eastward of La Soufriere of St. Vincent.

Eton, Bucks, May 27. T. C. PORTER.

III.

The dust from the Soufrière, which fell in Barbados on May 7 and 8, appears to be composed of fragments of glassy and pumiceous lava, broken crystals of plagioclase felspar, augite and hypersthene, much magnetite, often in perfect octahedra, and a very few crystals of brown hornblende. The felspars range in specific gravity from labradorite to anorthite. Hypersthene is the predominating coloured silicate.

Dust from the eruption of 1812 also collected in Barbados is of much finer grain, but evidently composed of the same minerals with the green augite in smaller proportion.

The magma appears to have been of the nature of hypersthene-andesite, a rock exceedingly common among the recent lavas of American volcanoes. Further, the magma seems to have remained practically unchanged in composition during the Soufrière's ninety years of dormancy.

University of Edinburgh. J. D. FALCONER.

RECORDS OF RECENT ERUPTIONS.

FROM accounts which have been published during the past week, some additional details referring to the character and effects of the recent volcanic eruptions in the West Indies have become available and are here brought together.

A letter from Mr. A. D. Whatman, one of the members of the Government relief expedition to Martinique, describes some of the events as related to him by one of the survivors of the steamship *Roraima*, which was about 150 yards from the shore when the catastrophe occurred at St. Pierre. It appears that a little before 8 a.m. on May 8 an explosion was heard, and immediately the whole place was in darkness. At the same moment white-hot sand began to fall, which penetrated everywhere like snow, and immediately killed everyone on deck. After about an hour and a half the fall of white-hot ash stopped.

Referring to the condition of St. Pierre when he visited it, Mr. Whatman says :—

There was no lava thrown out; nothing but this fine sand, which was evidently white hot. Judging from what the few saved said and from what I myself saw and could judge from the position of the bodies, I have little doubt that everyone who was not under cover at the time the sand began to fall was killed in less than two minutes. The rest must have survived for a very short time longer, as they must have been quickly suffocated by the heat from the falling sand, not to mention the fact that the whole town must have caught fire at the same moment. A tremendous blast of air must have crossed from north to south, as all trees have been uprooted, and their remains are all pointing with roots towards the volcano. The lighthouse also fell in the same direction.

A message from the Acting Governor of Martinique states that from the further exploration of St. Pierre it would seem as if the southern portion of the town was destroyed by an as yet unexplained phenomenon, which acted with lightning-like rapidity, and has left traces as of a violent storm sweeping from north to south. The rain of ash which preceded, accompanied and followed this phenomenon covered the surface of the land to a depth of between twenty-five and thirty centimetres. The northern part of St. Pierre is buried beneath a mass of mud.

From the *Observer* we learn that the Deputy-Mayor of St. Martinique, who left St. Pierre just fifty minutes before the catastrophe took place, and was a witness of all the circumstances which led up to it, has given a new account of the condition of the volcano before the eruption. He says that shortly before St. Pierre was overwhelmed, immense fissures, caused by the earthquake, appeared in the side of Mont Pelée, reaching down to the edge of the sea. Into these the sea water rushed, and it was the contact between the water and the burning lava from the volcano which caused Mont Pelée practically to blow up like an overheated boiler.

The *Standard* records some observations made by Prof. R. T. Hill, a member of the United States Geological Survey, who went with Prof. Heilprin to Martinique to observe the volcanic phenomena and effects. Prof. Hill made his observations at a distance of five miles from Mont Pelée. On May 26 he observed what is usually described as lightning playing through the mushroom-shaped cloud overhead, like a sheet covering the country up to ten miles from the crater. These flashes occurred with alarming frequency, and they followed distinctly horizontal paths, hence they are believed to be effects produced by the explosive combustion of gases leaving the Mont Pelée crater.

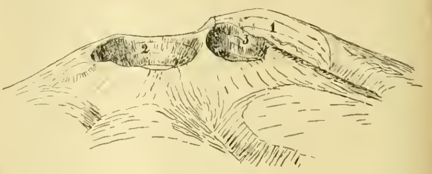

FIG. 1.

Mr. G. Kennan, who reached the new crater near Ajoupabouillon, at the head of the river Falaise, which is boiling hot, reports that a large section of the side of Mont Pelée has fallen, leaving a huge perpendicular cliff, in which there are five immense tunnels or cavities.

Dr. Hans Reusch, director of the Geological Survey of Norway, has sent us the following description of the crater of the Soufrière of St. Vincent as he found it in 1892 :—

During a visit to the West Indies in 1892 I ascended the volcano now so much spoken of on the northern end of St. Vincent. When I was at the top I drew the accompanying bird's eye view from the south (Fig. 1).

It may be of some interest to compare this with the changes which undoubtedly have taken place during the recent eruptions. The crater numbered 1 is the remnant of an old very wide crater—some kind of Monte Somma (of Vesuvius). The height is given on the maps as 4043 feet above the sea. No. 2 is "the big crater," the breadth of which I estimated to be 1 kilometre. The bottom is filled with a lake of bluish-green opaque water, the colour being due to sulphur in fine powder. I calculated the vertical distance from the lake to the lowest point of the brim to be about 150 metres. The dip of the inner sides of the crater was about 60°. The slopes were mostly covered with bushes, but a stratification of the tufa was marked by horizontal lines. The small crater, No. 3, is about half as large as the other one, but comparatively deep. The stratification of its sides is inclined at about 20° in a northerly direction. It is a "steam hole" blown out somewhat to the side of the chief place of eruption. On the bottom lies a little pond of clear water, the rest of the bottom being covered with loose material washed down from the sides of the crater. The only sign of volcanic activity was a little smoke now and then

[1] One opaque crystal only seemed to evolve a slow stream of bubbles, as if they came from a cavity in it. Whatever the gas was it dissolved in the liquid very rapidly, the bubbles visibly diminishing almost to nothing in ascending through the very shallow stratum of liquid above the crystal.

issuing from a small cleft near the pond; a sulphurous odour was also perceptible. The great eruption in 1812 was exclusively, or at least in greater part, an ash-eruption, as no lava stream was seen on the exterior of the mountain. A few insignificant beds of andesitic lava still occur interstratified in the tufa.

Someone told me that the island was rising slowly out of the sea on its western and sinking on its opposite side; this, however, was denied by others. If any change of importance has taken place on the western side during the last convulsion of Nature, it should not be difficult to ascertain the fact and determine the amount of change of level. I went in a boat along the coast from Château Belair to Kingstown and observed that where the coast consisted of tufa (not where it was formed of solid lava or coarse volcanic agglomerate) it displayed a kind of strandline or beach-shelf. It was a horizontal or slowly dipping platform about a yard broad. Fig. 2 shows the shelf along a promontory seen from some height, Fig. 3 represents a small island surrounded with its beach-shelf, while Fig. 4 gives a diagrammatic section of the shelf.

The sea at high water rises about one foot above the shelf and sinks at low water about 2 feet underneath it. At ebb-tide the outer slope is seen to be covered with seaweed (at X in the diagram), as far up as the sea rises the inner wall (at Y) is covered with a crust of calcareous matter consisting of serpulites and the remains of other sea animals. I cannot suppose that this peculiar beach was due solely to the action of the waves. Organic life has probably had something to do with it, the rate of recession of the cliff being comparatively rapid where the animals lived, while on the other hand the seaweed has been to a certain extent

FIG. 2.

FIG. 3.

FIG. 4.

protective. In any case this beach-shelf should be of good service in determining whether any sudden change of level has taken place during the latest eruptions.

Christiania. HANS REUSCH.

A comparison of Dr. Reusch's observations with those which, it is hoped, will shortly be obtained, should be of value in showing the changes which have occurred.

The Paris Academy of Sciences has decided to send a special scientific expedition to the scènes of the eruptions. The expedition will sail on June 9.

In extension of the diary of recent volcanic events already published in these columns, we give a record of occurrences reported during the past week.

May 10, *Tacoma.*—Mount Redoubt, in Cook Inlet country, Washington State, has been pouring forth dense volumes of smoke for a week past, and a few nights ago became luminous. Volcanic ashes have been falling for several days, and the snow near the mountain is covered with ashes. The last eruption of Mount Redoubt was in 1867.

May 28.—A sharp shock of earthquake was felt in the Cape Peninsula at midnight.

May 28, *Fort de France.*—There was a tremendous explosion, followed by a cloud of black smoke, from Mont Pelée at 8.45 this morning.

May 29, *Fort de France.*—The eruptions of Mont Pelée have become more frequent, although less violent.

May 30, *Kingstown* (*St. Vincent*).—There was a fresh eruption of the volcano La Soufrière this morning. It was accompanied by a thunderous noise and trembling of the earth, while volumes of vapour were emitted from the crater. The eruption lasted an hour.

May 30, *Fort de France.*—Cable communication with St. Thomas was again broken. A violent eruption of Mont Pelée took place at 2 p.m. It is reported that the craters on the north side of the mountain are pouring out torrents of mud.

May 31, *Fort de France.*—Detonations were heard from the volcano this morning, and volumes of smoke were emitted. The Rivière Blanche is again a torrent of steaming hot mud.

May 31, *Kingston.*—During the past week Jamaica has been experiencing magnificent sunsets, the colours being extraordinarily rich and beautiful. The phenomenon is due to the volcanic dust in the atmosphere.

May 31, *Athens.*—For some days past earthquake shocks have been repeatedly felt in various parts of Greece.

DR. HENRI FILHOL.

DOCTOR HENRI FILHOL, professor of comparative anatomy at the Museum of Natural History, Paris, died on April 28 at the relatively early age of fifty-nine. A naturalist and palæontologist of the first rank, he will assuredly be lamented by a large circle of friends, not only in his native land, but also in this and other countries, his many and important contributions to our knowledge of both living and extinct animals being of world-wide interest.

Henri Filhol, son of Edouard Filhol, the famous chemist of Toulouse, was born in that town in the year 1843. Having studied for the medical profession, he early obtained his degree of doctor of medicine. His first contribution to science appears to have been in 1863, when he was about twenty years of age, for at that time was published, in conjunction with M. F. Garrigou, his paper on "L'Age de la Pierre dans les Cavernes de la Vallée de Tarascon (Ariége)" (*Comptes rendus*, lvii.). The French commission sent out for the study of the transit of Venus in 1875 included Dr. H. Filhol among its members; and the fact that in 1876 he received the Lalande-Guérineau prize of the Academy of Sciences is evidence of his confrères' appreciation of these early labours for science.

One of Dr. Filhol's most remarkable pieces of work was his "Recherches sur les Phosphorites du Quercy" (*Ann. Sci. Géol.* 1876, t. vii. pp. 220, pls. 10–36, and 1877, t. viii. pp. 1–273 and 297–340, pls. 1–26). In this are described the remarkable deposits of phosphate of lime, of Upper Eocene age, which occur as great pockets in Jurassic beds in the departments of the Lot, of the Tarn and Garonne, and of the Aveyron; then follows, as the subtitle of the work says, an account of the fossils met with in these deposits and especially the Mammalia. Numerous new forms are brought to light, and others critically revised, in this memoir of more than 500 pages and 52 plates.

Another work of similar character is the "Étude des Mammifères Fossiles de Saint-Gérand le Puy (Allier)" (*Ann. Sci. Géol.* 1879, t. x., and 1880, t. xi.), which occupies some 338 pages and 51 plates, and was the result of studying numerous collections of fossils, made during many years, from these Lower Miocene deposits. Here again numerous forms are described, many being regarded as new to science. A third work is entitled "Étude des Mammifères Fossiles de Ronzon" (*Ann. Sci. Géol.* 1881, t. xii. pp. 270, pls. 6–31). The locality is near the village of Puy, and the calcareous marl which has yielded this great assemblage of fossil vertebrata is believed to be of Miocene age. Many mammalian remains from the locality had already been collected and described by M. Aymard (1856); but not only are these critically revised in the light of new material, but again new forms are made known. A fourth piece of work of the same kind is the "Études sur les Mammifères Fossiles de Sansan" (*Ann. Sci. Géol.* 1891, t. xxi. pp. 314, pls. 46). M. E. Lartet had begun the study of the remains from this Miocene deposit, but died suddenly, leaving the work uncompleted. Dr. Filhol, taking up the study of the extensive material preserved in the Paris Museum, and with the help of additional specimens collected by himself under the auspices of the same museum, produced this important memoir.

These four volumes of painstaking work, including more than 1400 pages and 174 plates, would alone have constituted a most important contribution to natural knowledge, reflecting high honour upon the author; but this is only a part of the work which he accomplished. He had a lively interest in deep-sea exploration, and, as a member of the commission, took a prominent part in the dredgings of the *Talisman* expedition in the year 1883. The results of this and of the *Travailleur* work were made known in his "La Vie au fond des Mers" in 1885. Another work published about this time is the "Faune des Crustacés de la Nouvelle-Zélande," and his "Zoologie Descriptive" was issued in the same year. In 1893 he published, in conjunction with M. Grandidier, "Observations relatives aux ossements d'Hippopotames trouvés dans le Marais d'Ambolisatra à Madagascar" (*Ann. Sci. Nat. Zoologie*, 1893, ser. vii. vol. xvi., pp. 151–190, pls. 7–15). In this memoir are described the remains of the remarkable pigmy hippopotamus found by M. Grandidier, from which place also Dr. Forsyth Major obtained the material recently described by him in the *Geological Magazine*.

Besides the examples of Dr. Filhol's labours above alluded to, he made many other contributions to zoology and palæontology. Under his name will be found, in the Royal Society's catalogue, upwards of fifty papers published before the year 1883, and about as many more have been published since that date. This noble record has been appreciated by his fellow workers throughout the world, and has not been without hearty recognition in his own country; for besides the Lalande-Guérineau prize in 1876, already mentioned, he was awarded the gold medal of the Scientific Congress of the Sorbonne in 1879, the chief prize for physical and natural science of the Academy of Sciences; he was the recipient of the Petit-d'Hormoy prize in 1883, and received the decoration of the Legion of Honour in 1886.

Dr. H. Filhol at one time held the chair of zoology of the Faculty of Sciences of Toulouse, his native town; in 1885 he became subdirector, and subsequently director, of the laboratory of anatomical zoology at the Museum of Natural History, Paris; more recently he was appointed to the professorship of comparative anatomy at the same national institution, and continued to hold that post until the time of his death.

NOTES.

THE German Emperor has, with the consent of the British Government, appointed Sir Joseph Dalton Hooker, G.C.S.I., C.B., late Director of the Royal Botanic Gardens at Kew, a foreign Knight of the Order *Pour le Mérite* for Science and Arts. It has been officially decided that the regulations regarding foreign decorations do not apply to this order.

LORD RAYLEIGH has been elected a corresponding member of the section of natural sciences of the Imperial Academy of Sciences of Vienna.

MR. J. B. SCRIVENOR has been appointed geologist on the Geological Survey, and Mr. D. A. MacAlister has been appointed temporarily to investigate metalliferous mines.

WE learn that Lord Salisbury has asked the President of the Board of Trade to receive a deputation from the Institution of Electrical Engineers on the subject of the present unfavourable condition of the law relating to electric lighting and traction (see NATURE, vol. lxvi. p. 35). The deputation is to wait on Mr. Gerald Balfour to-day (Thursday). In view of the backwardness of this country in electrical engineering and of the large degree in which this backwardness is due to restrictive legislation, it is to be hoped that the Government may be induced to introduce more rational laws without delay.

THE Berlin correspondent of the *Times* writes that experiments were carried out last year at the General Telegraph Office in Berlin with a new system of octoplex typographic telegraphy. It is claimed that this system will enable twenty operators to send 18,000 words an hour through a single wire. The despatching instrument is of the typewriter form, and to telegraph any letter it is only necessary to depress a single key. The receiving instrument prints the message on a sheet of paper (not on a tape), and this can be immediately detached and forwarded to its proper destination. An installation to enable communication between Hamburg and Frankfurt by this system is being put up, and will shortly come into use. Further particulars and developments will be awaited with interest. The invention is due to the late Prof. H. A. Rowland, of Baltimore.

IT is reported that Mr. Thomas A. Edison has been experimenting with a view to the invention of a storage battery to enable automobiles to run 100 miles without recharging. As soon as a 5000 miles endurance test, which is about to be started, is completed, he will begin the manufacture of storage batteries for the use of automobiles, launches and street cars. It is understood that Mr. Edison's invention will also greatly diminish the weight of automobiles.

THE fifty-first annual meeting of the American Association for the Advancement of Science will be held at Pittsburgh from June 28 to July 3. At the first general session the retiring president, Dr. C. S. Minot, will introduce the president-elect, Prof. Asaph Hall. The presidents of sections will deliver their addresses on Monday, June 30, and Dr. Minot will give his address, as retiring president, on the following day, at the Carnegie Museum. The programme of the work of the sections has not yet been published.

THE forty-seventh annual exhibition of the Royal Photographic Society will be held from September 29 to November 4. There will be five sections, namely, (1) selected pictorial photographs; (2) general professional work; (3) photographic apparatus and materials; (4) photo-mechanical processes of reproduction; (5) scientific photography and photography in its technical applications. The judges of sections four and five will be Sir William Abney, K.C.B., F.R.S., Mr. Chapman Jones and Mr. E. Sanger Shepherd.

THE *Bulletin* of the Belgian Academy contains an obituary notice by M. C. Le Paige of M. François Deruyts, who died in February last. M. Deruyts was an ardent student of pure geometry. On leaving the University he published a remarkable dissertation on the theory of involution and unicursal homography, and this formed the nucleus for a series of investigations dealing with the geometry of hyperspaces and the determination of the singular elements in an involution of any order. From general theorems, numerous elegant applications to special curves and surfaces were deduced. M. Deruyts also possessed an intimate knowledge of analysis and mechanics.

AN International Shipbuilding Congress in connection with the Düsseldorf Exhibition was opened on Monday by the Crown Prince of Germany. More than 550 delegates are in attendance. Of foreign countries Great Britain is most numerously represented. The Institution of Naval Architects is represented by the Earl of Glasgow (president), Lord Brassey, Messrs. Elgar, Thornycroft, Yarrow, and others. The Crown Prince, in declaring the Congress open, expressed the regret of his father, the Emperor, that his Majesty was unable to be present, and hoped that the deliberations of the Congress would be fruitful in good results.

THE Board of Agriculture has given notice that the Colorado beetle has again made its appearance at Tilbury. Potato growers are, therefore, requested to examine their plants and

to send to the Board without delay for identification specimens of any insects suspected to be the Colorado beetle. The Board will be pleased to supply copies of a leaflet, with a coloured illustration of the beetle, post free and free of charge upon application. Letters or packets containing specimens, and applications for leaflets, should be addressed to the Secretary, Board of Agriculture, 4 Whitehall Place, London, S.W., and need not be stamped.

AN interesting ceremony was performed at Chamounix on May 19, M. Joseph Valat, the founder of the Roches-Rouges Observatory, being in the chair. The bust of Charles Durier, a former president of the French Alpine Club, was presented to M. Simon, the manager, by M. Schrader, the president of the society. A letter was read from M. Janssen, who was prevented by reasons of health from being present. M. Simon was surrounded by a group formed by the Mont Blanc guides, who ascend Mont Blanc every week in order to bring back to Chamounix the automatic readings registered at the Janssen Observatory. Speeches were delivered by MM. Chautemps, the member for Chamounix to the Chambre des Députés, Morel, Fredel, president of the Mont Blanc section of the Alpine Club, Paul Joanne, an intimate friend of Charles Durier, Prideux of the Academy of Sciences, and other influential members of the Alpine Club.

AT the recent general meeting of the Paris Geographical Society, the following prizes awarded for this year were announced :—The chief gold medal of the Society to Captain Joalland, for the Joalland-Meynier expedition to Central Africa, with a silver-gilt reproduction of the medal to Captain Meynier. The Herbet-Fournet prize, a gold medal and 6000 francs, to Governor Emile Gentil, for work on the Tchad (1895–1901). Silver medals are awarded to the principal officers of M. Gentil's expedition. The Ducros-Aubert prize, three gold medals, to M. V. A. Bernard and Dr. Huot, for the Chari-Sangha exploration, and to M. Ch. Perdrizet, for his work in West Africa. The Conrad Malte-Brun prize, gold medal, to Captain Ch.-Lemaire, for the scientific exploration of Katanga. The Henri Duveyrier prize, gold medal, to Captain E. A. Lenfant, for scientific explorations on the Senegal and Niger. The Louis Bourbonnaud prize, gold medal, to M. P. Bons d'Anty, for explorations in South China. The Jean-Baptiste Morot prize, gold medal, to Captain E. Julien, for explorations in the basin of the Oubanghi. The Léon Dewez prize, gold medal, to M. Hugues Krafft, for his journey into Russian Turkestan. The Pierre-Félix Fournier prize, special medal and 1300 francs, to M. H. Béraldi, for his book "Cent Ans aux Pyrénées." Silver gilt medal of the Society to MM. Marcel Dubois and Auguste Terrier, for their book "Un Siècle d'expansion coloniale." The Alphonse de Montherot prize, silver medal, to M. Georges Brousseau, for his explorations on the Congo. The Charles Grad prize, two silver medals, to M. Maurice Superville and Lieut. Bos, for their exploration of the Kotto. The Alexandre Boutroux prize, silver medal, to M. Albert Lesieur, for his explorations on the French Congo. The J. C. Janssen prize, silver medal, to M. Emile Belloc, for his study of the physical geography of the Pyrenees. The William Huber prize, silver medal, to M. de Martonne, for his geographical studies. The Jomard prize to M. Cl. Madrolle, for his book "Histoire de la Compagnie des Indes en Chine." Competitive prizes of the Society, two silver medals, each accompanied with 400 francs, to MM. P. Pasquier and M. A. Breschin.

ON Thursday evening last the members of the Camera Club and their guests were assembled to listen to a discourse by Dr. E. F. Grün on the new fluid lens with which he has recently been obtaining some very excellent photographs of theatrical and other night scenes. The use of a fluid lens is a very old idea, but it soon fell out of use when homogeneous glass could be made properly and the combination of flint and crown successfully mated. The object of using fluid in lenses at this early time was simply to overcome certain optical deficiencies of the single glass lens. Dr. Grün's idea in adopting this form of lens is to increase very considerably the rapidity of its action, and so successful has he been that he can produce very excellent photographs with short exposures with ordinary night illumination, his lenses working at *f.* 1·4 and even *f.* 0·5. The slides made from the photographs he has taken showed several snapshots taken at different theatres without any previous preparation either as regards the actors and actresses, or the stage illumination, and these were quite sufficient to give one an idea of the important future for such a lens. One of the chief points in the lens is the great depth of focus which is shown in the individual pictures, for not only are the performers in front of the stage in focus, but the scenery at the back is quite sharp as well. The very great rapidity of the lens led Dr. Grün to attempt to take kinematograph pictures of stage performances. The results, although not of a very high order, showed, however, that with a little more experiment just as good pictures of night scenes can be secured as are displayed to-day in kinematograph pictures taken in daylight. There is little doubt that Dr. Grün has indicated the great possibilities of his new lens, and many scenes which could not be depicted on account of their apparent lack of sufficiently brilliant illumination may now be caught in the meshes of this photographic net.

WITH reference to the correspondence which has recently been appearing in these columns on the misuse of coal, we see from last week's *Electrical Review* that a company has just been incorporated in America for the commercial fixation of nitrogen. The company is to erect a factory at Niagara, where it already has one commercial unit in operation. This consists of a chamber about 10 feet high, through which cool dry air is passed. The air is subjected to the influence of electric discharge in the form of small-current high tension arcs, whereby oxides of nitrogen are formed. These oxides are led to an absorption tower, where they are brought into contact with a suitable compound of a substance of which the nitrate is desired; caustic soda or potash, for example, are used for the preparation of sodium and potassium nitrate respectively. If led into water, nitric acid can be obtained. It is said that part of the object of Lord Kelvin's recent visit to the States was to see the working of the process, and that he was greatly interested and much impressed by its success.

IN a short note contributed to the *Atti dei Lincei*, xi. 9, Signor G. Celoria urges the desirability of including the teaching of astronomy in the curriculum of every Italian university and of making the subject a compulsory part of the science courses. At present the regulations require astronomical classes to be held at all universities which possess an observatory, but Signor Celoria considers that much useful teaching may be given without the help of instruments, and further, that the present limitation tends to confine the study of astronomy to its purely practical aspect.

IN the University of Colorado *Studies*, Messrs. William Duane and Charles A. Lory describe a simple electric thermostat for keeping the temperature of a bath constant to within a thousandth of a degree Centigrade for a considerable time. The heat is supplied by an electric current, which in the case of a conducting liquid flows through the liquid itself, and in the case of a non-conducting fluid flows through wires suspended in the bath. A system of tubes containing a liquid with a large temperature coefficient of expansion is placed in the bath, and by means of a suitable mechanism the expansion of this liquid

interrupts or reduces the strength of the heating current when the required temperature has been reached. It might be thought that this arrangement would give rise to considerable fluctuations of temperature with the making and breaking of the current, but it is found that the makes and breaks follow each other so rapidly, often two, three or even more times in a second, that the variations cannot be detected with a differential thermometer which ought to be sensitive to within a two-thousandth part of a degree.

IN the *Revue générale des Sciences* of April 30, M. Nordmann proposes a theory of the propagation of electric force from the sun into space which is based on the assumption that Hertzian waves are emitted from the surface of our luminary, and that the emission of these electric waves must be particularly intense at epochs of maximum solar activity. M. Nordmann admits that hitherto attempts to discover Hertzian waves in the solar radiation have led to a negative result; but, in his opinion, this may be explained by the copious absorption of the electric undulations in the higher layers of our atmosphere. On this hypothetical basis the theory attempts an explanation of cometary phenomena, of terrestrial magnetism, and of the luminosity of matter in the nebulæ and in the vicinity of temporary stars. M. Nordmann's paper thus covers the same ground as the previous researches of Prof. Arrhenius. But the distinguished Swedish physicist advocates the theory of corpuscular electric emission, and M. Nordmann endeavours to show that some grave objections may be urged against this point of view, and that, on the whole, the cosmical phenomena here considered are better explained by the undulatory electric theory of Maxwell and Hertz.

MESSRS. ROSENBERG AND CO. have submitted to us for examination a portable Röntgen ray outfit which they have produced. The outfit consists of a 10-inch spark coil of special construction with tube, holder, fluorescope and accessories, the whole fitted in a strong box measuring 2 feet 1 inch × 11 inches × 14 inches. The coil when tested with a 12-volt accumulator sparked well at 10½ inches—the distance between the discharging pillars. The break has large platinum points, and the sparking can be regulated with great nicety. For those who prefer an electrolytic break there is a means of throwing out the condenser, and other breaks can be used with little alteration. We should advise those who wish to use this apparatus continuously to have a separate tube-holder, as that supplied with the outfit is fixed to the box, and consequently would render the operator liable to "X-ray dermatitis." The screen is thickly and evenly coated, and measures 7 × 10 inches. One advantage of this outfit is that when the box is locked everything is safe, as all attachments are covered up and cannot possibly be damaged. There is ample room inside for plates, volt- and am-meters, and the box contains all that is required except the accumulator. As being trustworthy, cheap and handy, the outfit can be recommended for the purpose for which it is intended, and those who have not made a special study of X-ray work will find little difficulty in obtaining good results with it.

A DISCUSSION of the rainfall of Saxony and the Thuringian provinces, with coloured map, by Dr. G. Hellmann, has been published on the same plan as that adopted for several of the other German States which have preceded it. The work is based upon the results of ten years' observations, and forms a valuable contribution to the rainfall statistics of that part of Europe. The mean annual rainfall for the whole area is rather more than 23 inches, but in the neighbourhood of the Hartz Mountains to the west and the Thuringian forests to the south, the annual fall exceeds double that amount; in the central parts of the province of Saxony the rainfall does not exceed 20 inches. The discussion gives full details of the monthly values and of the greatest fall in various short intervals of time.

THE Royal Meteorological Society has published a fifth edition of "Hints to Meteorological Observers," by Mr. W. Marriott. This useful little work, consisting of only sixty pages, of which twenty pages are tables of reduction, contains all that is necessary for the purpose for which it is intended, and, what we think is of much importance, nothing that is not necessary. Among the chief additions to this new issue are instructions for the construction of thermometer screens for tropical countries, a description of Mr. Dines's pressure tube anemometers, which are likely to come into more general use, and pictures to accompany the cloud nomenclature adopted by the International Meteorological Committee. The Meteorological Congress held at Rome in 1879 expressed the opinion that an international dictionary of meteorology should be published, and as a first step towards the carrying out of this resolution a "Glossary of Meteorological Terms" has been added, which will be of considerable assistance, especially to younger observers.

THE annual report issued by Mr. J. B. Carruthers, Government mycologist at the Royal Botanic Gardens, Ceylon, records important work completed or in progress. Of fungal diseases, those which attack the tea plant naturally receive the most attention. The most important of the leaf diseases, known as grey blight and caused by *Pestalozzia Guepini*, seems to be confined to the tea shrub, as it has not been found on the leaves of plants growing in the jungle or elsewhere in the vicinity of diseased tea plants. Experiments are being carried on to determine how far the disease may be carried by spores, and the liability of weak plants to succumb to the disease. The discovery of the ascus-bearing fruit on the stem reveals a method by which the fungus can perpetuate itself. Under ordinary circumstances it is confined to the leaf, but if it can attain a vigorous state of development it may grow down the leaf-stalk into the stem and there form its fruit. A destructive root disease is due to *Rosellinia radiciperda*, a fungus which can grow both as a saprophyte and as a parasite. It starts on dead timber, such as the root-tissues of a dead Symplocos, and when the soil is thoroughly wet it can travel and spread to the roots of living plants, notably the tea plant. An effectual remedy consists in cutting deep drains at least a foot broad. Other subjects investigated were cacao canker, finger and toe disease, dry rot and pollination of cacao flowers.

THE *Journal* of the Anthropological Institute is highly creditable both to the Institute and to Britain; it is, as a matter of fact, the best extant journal that deals with anthropology in a comprehensive manner, and it is to be regretted that it does not meet with the circulation that is deserved by its interest and value. The range of the second part of vol. xxxi. extends from Wiltshire palæoliths and Irish copper celts to notes on Malay metal work and a classification of Sarawak swords; there are papers on African and Papuan craniology, trephining in Melanesia, colour vision of the natives of Upper Egypt, early Egyptian racial types, an ethnographical account of the natives of Manipur and of the Paraguayan Chaco, the animal cults of Sarawak, and a memorandum on the languages of the Philippines. Several of these articles are fully illustrated with most excellent plates, and it will be noticed that practically the whole range of anthropology is covered by original articles in the current number of the *Journal*.

IT has long been suspected that certain prehistoric peoples trephined the skull of living persons for surgical reasons, and now we have a definite modern instance from Melanesia. The Rev. J. A. Crump, in his paper on "Trephining in the South Seas"

(*Journal* of the Anthropological Institute, vol. xxxi. p. 167), states that in New Britain the local wizard trephines with a piece of shell or with a flake of obsidian in cases of fracture caused by a sling stone. This operation is described; the number of deaths is about 20 per cent., most of these resulting from the first injury and not from any complication after the operation. Complete recovery takes place in two or three weeks' time. In New Ireland the operation is performed, not only in the case of fracture, but where there is epilepsy and certain forms of insanity as the result of pressure on the brain. After trephining has been performed, there is frequent partial temporary paralysis, which almost invariably passes away. Idiotcy is an occasional result also. But the natives affirm that while the cures of insanity and epilepsy are many, the instances where either malady supervenes after the operation are exceedingly few. Dr. Victor Horsley's discussion of this paper lends it additional interest.

ONE of the latest departures of the experimental psychologist consists in prodding people with a pointed instrument when they are asleep to find out how much excitation is required before they begin to move, and how much it takes to wake them up. This method is embodied in a paper on "Experimental Investigations on the Depth of Sleep," by Drs. Sante de Sanctis and U. Neyroz, of Rome, a translation of which is given in the *Psychological Review* for May. The instrument employed is called a Griessbach ethesiometer (made by Brändli, of Basle), and may be used with either a sharp or blunt point. It measures the stimulus necessary to induce subconscious reaction, and that applied at the waking point. Four normal subjects, all relatives of the writer of the paper, were experimented on for about six consecutive months, and afterwards five subjects, mostly epileptic, were operated on, and from the results obtained curves were drawn showing the relative depth of sleep, as measured by the stimuli required, after the subject had been allowed to sleep for various lengths of time. The curves are all of zigzag form, and the experiments may perhaps suggest a practical application in the case of subjects who find it hard to wake in the morning, and who may overcome the difficulty by timing their sleep so that the waking point is at a minimum when they wish to rise.

IN the Report of the Marlborough College Natural History Society for 1901, Mr. S. B. Dixon gives an account of the recent important discovery of Palæolithic flint implements at Knowle, near Savernake Forest. The state of the Society appears to be flourishing, the entomological section showing a specially good record of work. The report is illustrated by some excellent reproductions from photographs of local scenery.

ACCORDING to the Berlin correspondent of the *Times*, an international agreement for the protection of birds useful to agriculture was signed at Paris on March 19, the contracting parties being Belgium, France, Greece, Lichtenstein, Luxemburg, Monaco, Austria-Hungary, Portugal, Sweden, Switzerland and Spain. Certain insectivorous species and others scheduled as being specially useful to agriculture are to receive unconditional protection, the destruction of the birds themselves, or of their nests and eggs, being prohibited at all seasons. It is noticeable that Italy, where numbers of useful birds are annually killed during migration, does not appear among the signatories.

IN the introductory comments to the second (May) number of the *Field Naturalist's Quarterly*, the editor discusses the proper sphere of work for local natural history societies. The importance of taking cognisance of all subjects connected with local biology is strongly urged, as the specialists are sure to look after their own interests, and will, when necessary, institute sections devoted to their own favourite subjects. "The great justification of a field club ought to be that it is doing work that is otherwise neglected. There is not an area of ten miles square in this country but what offers some subject of investigation." Several of the articles in this number deal with the habits and movements of animals in spring, and the illustrations include some interesting photographs of nests and eggs.

WE have received the "Catalogue of the Educational Collection of Minerals belonging to the West Ham Municipal Technical Institute," compiled by Dr. H. A. Auden. From a high scientific standpoint the classification here adopted of minerals, according to electronegative constituents, will no doubt meet with the approval of the learned. Under this arrangement, zincite, corundum and hæmatite (as simple oxides) follow one another; and the same is the case with anhydrous carbonates, such as aragonite, witherite, strontianite and cerussite. For purposes of technical education a practical grouping would appear more desirable. The author's object is, however, to illustrate the systematic grouping of mineral specimens, and in the "addenda" he enumerates the principal metals and ores, jewels and other minerals of industrial importance. An index would have added to the value of this useful work.

A NEW general method for the synthesis of fatty aldehydes is described by MM. L. Bouveault and A. Wahl in the current number of the *Comptes rendus*. It was shown by Henry some time since that aldehydes of the fatty series could be readily condensed with nitromethane to form addition products, which the authors have now found to readily lose water to zinc chloride under suitable conditions, giving nitro-derivatives of substituted ethylenes. These are readily reduced by zinc and acetic acid to oximes, from which the aldehyde can be obtained without difficulty. The method has been applied by MM. Bouveault and Wahl to the synthesis of isobutylacetic aldehyde from the product of condensation of isovaleral with nitromethane, and of caprylic aldehyde from œnanthol.

SINCE the discovery of the remarkable compound of hydrogen and nitrogen known as hydrazoic acid, numerous modes of preparing it have been worked out, mostly through the use of somewhat complicated organic compounds. The only purely inorganic syntheses of this acid are those of Wislicenus from sodium amide and nitrous oxide and of Tanatar from hydrazine and nitrogen chloride. Tanatar now describes in the current number of the *Berichte* another elegant synthesis of this compound. A mixture of hydrazine sulphate and hydroxylamine hydrochloride is treated in acid solution with an oxidising agent and distilled, when hydrazoic acid passes over with the distillate. Hydrogen peroxide and chromic acid appear to give the best yields, which in no case exceed 30 per cent. of the theoretical amounts. Dihydroxylamine is probably the first product of oxidation, which then condenses with the hydrazine and is further oxidised to N_3H.

DR. M. BIAL has recently carried out some interesting experiments on the antiseptic properties of dilute solutions of acids, details of which are given in the last number of the *Zeitschrift für physikalische Chemie*. The observations were carried out with yeast cells, measurements of the retarding action of different acids on the development of the cells being made by observing the amount of carbon dioxide liberated from a solution of grape sugar. It is found that the concentrations of the solutions, which are just sufficient to check completely the development of the cells, are much smaller in the case of the strong acids like hydrochloric and sulphuric acids than in the case of weak acids such as acetic and butyric acids. The results, in fact, lead the author to conclude that the antiseptic power is essentially determined by the hydrogen ion which is contained in the acid solutions, and the electrolytic dissociation theory is able

to account for the observed phenomena in a satisfactory manner. As is required by this theory it is found that the addition of neutral acetates to a solution of acetic acid diminishes the antiseptic power of the acid, the concentration of the active component of the solution, the hydrogen ion, being under these circumstances reduced to a much smaller value.

NUMEROUS theories have been put forward at different times to account for the formation of natural paraffins, the one received with most favour being that due to Berthelot and developed by Mendeléeff in which the action of steam upon metallic carbides was regarded as the main source of the hydrocarbons. The chief stumbling block to this view was the difficulty of explaining the mode of formation of the naphthenes of the Russian oilfields. The researches of MM. Paul Sabatier and J. B. Senderens on the action of reduced nickel, iron and other metals upon hydrocarbons have now placed the "chemical" theory of petroleum formation on a firm experimental basis. By the direct hydrogenation of acetylene in the presence of nickel they have obtained liquid mixtures of hydrocarbons which can be made to correspond either with American or Caucasian petroleum by varying the conditions of the experiment. To account for the formation of petroleum it is thus sufficient to admit that there are in the depths of the earth free alkali metals and metallic carbides, which in contact with water give rise to mixtures of hydrogen and hydrocarbons. These gases encounter nickel, cobalt or iron in a finely divided state, and thus give rise to the mixtures of hydrocarbons forming natural petroleum.

THE additions to the Zoological Society's Gardens during the past week include a Bosman's Potto (*Perodicticus potto*) from West Africa, presented by Mr. Edward Straw; three American Bisons (*Bison americanus*) from North America, presented by H.G. the Duke of Bedford, K.G., P.Z.S.; three Darwin's Rheas (*Rhea darwini*) from Patagonia, a Red Ground Dove (*Geotrygon montana*) from South America, presented by Capt. John L. Marx, R.N.; two Garden's Night Herons (*Nycticorax gardeni*) from the Falkland Islands, presented by Mr. W. Grey Wilson, C.M.G.; an Algerian Tortoise (*Testudo ibera*) from North Africa, presented by Master C. Treverlyn Gill; a Silvery Gibbon (*Hylobates leuciscus*) from Java, deposited; six Ruddy Flamingoes (*Phoenicopterus ruber*) from North America, twenty Alpine Newts (*Molge alpestris*), twenty Newts (*Molge montandonii*) from Roumania, purchased; a Thar (*Hemitragus jemlaica*) born in the Gardens.

THE EQUATORIAL CURRENT ON JUPITER.

THAT differences occurred in the rate of motion of different markings on Jupiter was first discovered by Cassini in the seventeenth century. But other observers in later years appear to have neglected the systematic study of the planet. His disc was occasionally surveyed, it is true, and the positions of the belts described, but the details were not perseveringly followed. Telescopes were formerly of inordinate length and not very effective in performance, but what was accomplished by Cassini might also have been achieved by others. Jupiter's dimensions are such that comparatively small and imperfect instruments are capable of revealing the principal markings. Herschel never made a thorough investigation of the Jovian spots, though he obtained some observations in 1779 and recognised the difference in their motions. Until the last half of the nineteenth century the planet seems to have been generally surveyed in a desultory manner.

The apparition of the great red spot, however, revolutionised the existing state of things, for it was destined, not only to attract an immense amount of attention to itself, but to the whole visible phenomena presented by the surface markings of Jupiter. When this remarkable object first became perceptible it is not our purpose to inquire; it is certain, however, that as an exceptionally conspicuous feature it was widely observed during the last half of 1878.

It was long thought that the equatorial region of the planet supplied us with the most swiftly moving objects. This was, however, found to be a mistaken impression. The white and dark equatorial spots completed a rotation in about 5½ minutes less time than the red spot, and this meant a difference of velocity amounting to about 250 miles per hour. But it was soon seen that though the equatorial current is much more rapid than the rate exhibited in certain other latitudes, it does not equal the velocity of some other occasional markings in the northern hemisphere.

It is only our intention, however, to refer briefly to the equatorial markings observed during the last quarter of a century. But it must be confessed that the observations are not nearly so continuous and complete as the importance of the subject demands. The results have been sufficiently full for all purposes during the last few years, for several observers, including Mr. A. S. Williams, Rev. T. E. R. Phillips, Captain P. B. Molesworth and others, have obtained a mass of useful materials with reference to the equatorial current. And there seems no doubt that the investigation will be adequately maintained. It is chiefly to the continuity of the observations that we must look for the satisfactory elucidation of the phenomena presented. The equatorial spots have not, it is true, been always in strong evidence. In certain years they are liable to be almost, if not entirely, absent. The breaks, therefore, which occur amongst the accumulated observations are not always to be ascribed to negligence on the part of Jovian students.

At present the equatorial spots are both numerous and conspicuous, and it is to be hoped that a large addition to our observations will be effected during this opposition. The results for preceding years are very extensive and exhibit an irregular, though on the whole a decided, increase in the rotation period, but it would be premature to undertake the collection and reduction of all the materials. The observations must be prolonged over a much more lengthy interval before they can be expected to reveal the information we require. As observed at Bristol, the equatorial spots have shown the following variations in their rotation period, but satisfactory mean results from a number of different objects were only obtained during the last four oppositions:—

W. F. DENNING.

GERMAN PROGRESS IN OPTICAL WORK.[1]

I PURPOSE dealing with statistics compiled from information afforded me by two German firms and one Austrian, Messrs. Zeiss, Leitz and Reichert respectively, all of whom are well-known makers of microscopes, and the first named of many other optical instruments, including prismatic field glasses, of which, as is well known to you all, they were the originators. I must say that the figures quoted refer approximately to the end of the year 1899, since which date the average rate of increase has been more than maintained. Taking first the firm of Zeiss, in Jena, twenty years ago they employed fifty men; five years later the number had leaped up to 170, or more than three times as many; in another five years the number had practically been doubled, 327 being the precise number; yet another five years saw the number 580; while to-day (1899) they employ the astonishing number (astonishing, that is, for the class of instruments they manufacture) of 946 men, this grand total being made up as follows: theoretical staff, 22; office and dispatch, 36; mechanics, 322; opticians, 371; wood-workers, leather-

[1] Abridged report of a paper entitled "The Secret of German Progress," read before the Optical Society by Mr. Herbert F. Angus, Hon. Sec. of the Educational Committee of the Society.

workers, foundry-men, &c., 129. Of these men, 832 in number, including only those actually at work in the shops, 58, or 7 per cent., are foremen, and 178, or 27 per cent., are youths under eighteen. Turning now to Leitz, in Wetzlar, who, I may say, manufactures microscopes almost exclusively, we find the same steady progress, if not exhibited in such a striking degree. The numbers employed were: in 1879, 35; in 1884, 100; in 1889, 160; in 1894, 200; and at the present day (1899) 253. This number is divided up as follows: theoretical staff, 4; office and dispatch, 9; mechanics, 164; opticians, 60; case work, &c., 16. The foremen number 10, or 4·2 per cent., and the boys 18, or 7·25 per cent. of the total number actually employed in the shops, viz., 240. The firm of Reichert, in Vienna, although smaller, shows an almost identical rate of progress with that of Leitz, the numbers being: employed in 1879, 20; in 1884, 40; in 1889, 75; in 1894, 100; present day (1899), 150; of these, 3 form the theoretical staff, 8 are employed in the office and dispatch department; while of the remainder 120 are mechanics, 30 opticians and 8 case-makers, &c., the boys being 15 per cent. of the whole. I am afraid the numbers given in detail do not always agree with the totals, but I give them as received. . . . .

In the most successful of these firms, that of Zeiss, it will be noticed what a large percentage (27 per cent.) of boys is employed in comparison with the other two—Reichert 15 per cent., Leitz 7¼ per cent. It will also be noticed that the percentage (7 per cent.) of foremen is proportionately high. Herein, to my mind, lies the superiority of the firm of Zeiss over competitors of their own nationality, and much more so over us. I do not wish you to understand that I consider the number of boys employed by a firm an unfailing criterion of efficiency and progress; stated in this bald way the proposition is absurd, but, when we take this fact in conjunction with the well-known excellence of the productions of Zeiss (instruments than which no more delicate or difficult of manufacture can be found in the whole range of optics), when, I say, we take these two facts in conjunction, what is to be said of the organisation and system which allows of their coexistence? I think, therefore, that I may be allowed to say that the number of boys employed by Zeiss demonstrates their superiority, and not only that, but that it gives them a *potential* or *latent* power of progress, if I may use the expression. . . . .

I will premise one or two remarks which I have to make on the system of training adopted by saying that in Germany, as no doubt you all know, every young man is compelled by law on entering a trade to attend classes for instruction. Such classes the boys employed by Zeiss, of course, attend. A certain number of apprentices are taken who have, in addition, to attend higher classes, and from whom a higher standard of preliminary knowledge is required (that is, they must pass that examination which reduces the term of service in the army to one year). These higher classes are, however, open to the ordinary working boys, if they have sufficient brains to avail themselves of them. The teaching of optical subjects in the technical school of the town is practically under the firm's control, being subsidised by them, and some, if not all, of the teachers being drawn from the works; half the time spent at this school is during working hours, and is counted the same as attendance at the works. . . . .

This training of the boys and apprentices, the scientific management of the business and the experimental work is supervised by a staff of no less than eighteen mathematicians, physicists and chemists, each of whom holds a University degree; the salaries of these gentlemen, together with the cost of the experimental work undertaken, reach a total of from 6000*l.* to 10,000*l.* per annum. Here, then, in my opinion, you have the secret of German progress—a thorough well-grounded *elementary* training of the workmen, controlled and employed by those possessing a *real scientific* training.

A STEREOSCOPIC METHOD OF PHOTOGRAPHIC SURVEYING.[1]

IN the method proposed in this paper, photographs are taken, with a surveying camera, at a pair of points, the plates being exposed in the vertical plane passing through both stations. A réseau, or a graduated back frame, gives the means of measuring the coordinates of any point on the plates with reference to the optical axis of the camera. After development and fixing, the negatives, or positives from them, are viewed in a stereoscopic measuring machine, which, by combining the pictures, renders possible the instant identification of any point common to the pair of plates. Movable micrometer wires traverse each field, and pointings may be made simultaneously with both eyes. The readings of the micrometers, referred to the réseau, give the three coordinates of the point by direct multiplication by, or division from, constants for the plates, which depend only on the focal length of the camera lens and the length of the base. When a sufficient number of points have been plotted from their coordinates, contour lines may be drawn.

Theory of the Method.—Let A and B (Fig. 1) be the ends of

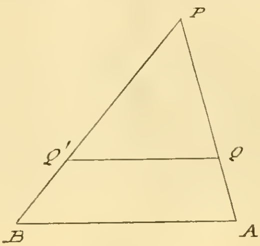

FIG. 1.

the base and Q and Q′ the positions on the photographs of any point P.

Take A as origin and A B as positive direction of x-axis.

Let (X, Y, Z) be the coordinates of P; $(x_a, f, z_a)(x_b, f, z_b)$ the coordinates of Q and Q′.

The equation of A P is:

$$\frac{x}{X} = \frac{y}{Y} = \frac{z}{Z},$$

and if we put $y = f$, we get:

$$x_a = \frac{f}{Y} X$$

$$z_a = \frac{f}{Y} Z.$$

Similarly the equation of B P is:

$$\frac{x-b}{X-b} = \frac{y}{Y} = \frac{z-h}{Z-h},$$

where b and h are the x and z coordinates of B.

Whence,

$$x_b = \frac{f}{Y}(X-b)+b$$

$$z_b = \frac{f}{Y}(Z-h)+h.$$

From these equations we find

$$x_a - x_b + b = \frac{bf}{Y} = e.$$

e is the *stereoscopic difference*, constant for points in any plane perpendicular to A y and vanishing for points at infinity.

The values of the coordinates of P follow:

$$Y = \frac{b}{e} f$$

$$X = \frac{b}{e} x_a$$

$$Z = \frac{b}{e} z_a.$$

A check is afforded by the values of X and Z derived from B P.

$$X = \frac{b}{e} x'_b - b$$

$$Z = \frac{b}{e} z'_b - h,$$

x'_b and z'_b denoting here the coordinates of Q′ referred to B.

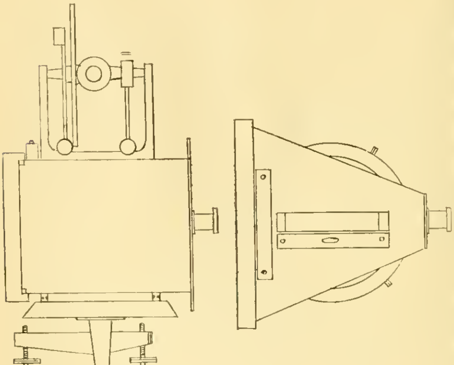
[1] A paper read on October 2, 1901, before the South African Philosophical Society, by Mr. H. G. Fourcade, Forest Department, Cape Town.

The measurement of the coordinates of a point being made independently on each plate, although simultaneously, it will be a sufficient condition for the viewing apparatus to make corresponding portions of the two pictures combine with or without change of perspective.

Using a magnifying optical system to view the pair of plates, the condition for distinct vision is that the two images of any point appear in a *corresponding plane of vision*, so that the visual rays meet in space. This condition evidently remains satisfied when the images are magnified, or when they are brought nearer together along a line parallel to that joining the nodal points of the two eyes, and for different distances between the viewing lenses or the eyes, since in all these cases the lines joining the two images of a point remain parallel to the eyes.

Surveying Camera.—The essential features are a camera on a theodolite base, and a telescope with its line of collimation at right angles to the optical axis of the camera, so that by changing pivots the orientation of the pair of plates is not affected by errors of inclination, collimation or graduation.

The photographic plate is pressed, during exposure, against a back frame in the focal plane of the camera lens, by a spring contrivance, similar to those used in other surveying cameras, which permits the shutter of the dark slide to be drawn and replaced. The réseau is hinged in front of the plate, its correct register being determined by geometrical contacts. It is impressed



Elevation Plan

FIG. 2.

upon the plate by exposure to sky light reflected through the camera lens and then moved out of the way for the exposure of the picture itself. A graduated front slide is used to displace the horizon line by moving the lens, but in normal circumstances it is set at the zero of its scale. Fig. 2 shows the general arrangement of the instrument.

Conditions to be satisfied.—One instrumental condition, sufficiently satisfied in construction, is that the front slide be parallel to the vertical réseau lines. Any defect in this respect is eliminated by determining the origin of the réseau coordinates and the focal length for different readings of the front scale.

The camera adjustments are: (1) Plane of réseau to be vertical. (2) Horizon line of réseau to be horizontal. These adjustments are made with the aid of a level, fitted with a Bohnenberger eye-piece.

The auxiliary level having been placed directly in front of the camera and its line of collimation made horizontal, the vertical axis of the camera is set vertical by reference to the level of the vertical circle. Then (1) is effected by turning the camera in altitude with the footscrews, and in azimuth, until the cross wires of the level coincide with their image reflected from the silvered back surface of the réseau when the bubble of the longitudinal level on the camera is adjusted to the centre of its run. Replace the front slide and lens and set again the vertical axis vertical. (2) is now effected by making the ends of the horizon line of the réseau coincide with the cross wires of the level in two positions, using for the purpose the side capstan-headed screws in the base. The transverse level on the camera is then adjusted, and the longitudinal level made perpendicular to the vertical axis by means of the front capstan-headed screws under the camera.

The theodolite adjustments, effected by ordinary methods, are: (3) Horizontal axis made perpendicular to vertical axis. (4) For collimation. (5) Horizontal axis made parallel with optical axis of camera. An approximate adjustment of (5) is sufficient.

Instrumental Constants.—These are (1) the zero of the front scale, (2) the zero of the réseau and coordinates of the R-points, and (3) the focal length. They may be determined in the usual manner, but it is convenient to first make the centre R-point coincide with the zero of the réseau coordinates by collimating directly upon the réseau plate when adjusting the camera with the help of an auxiliary level as already explained. In that case the lens requires to be adjustable horizontally as well as vertically.

The focal length f is found from the measurement of exposed plates containing the images of well-defined points of which the angular distances are known. Call α the angle between two points of which the horizontal coordinates are a and b. Then:

$$f = \frac{a-b}{2\tan\alpha} + \sqrt{\frac{(a-b)^2}{4\tan^2\alpha} - ab}.$$

Measurement of the Plates.—It is unnecessary in a preliminary note such as this is to enter into the construction of the measuring apparatus in much detail, as a description of actual instruments with examples of their use may fitly be given in a subsequent paper. A suitable machine would generally resemble those which have been used for the measurement of celestial photographs, and like such may be of various types.

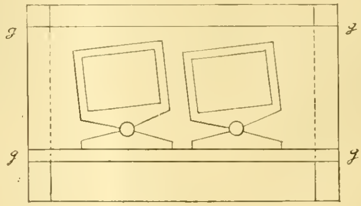


FIG. 3.

In the type now considered, the plates are set side by side at an inclination corresponding to that of the base line and at heights such that corresponding R-points are horizontal. Both plate-carriers can slide about in a horizontal direction on a stage formed of a sheet of plate glass g (Fig. 3), which itself can be moved vertically by a double rack and pinion. Any small error in the setting of the plate and in the fitting of the slides will be automatically corrected by the position of the eyes in front of the eye-pieces of the viewing microscopes and by their power of accommodation, and does not affect the accuracy of the measurements.

The measuring microscopes are of low power and include in their field at least one clear R-square of 1 centimetre side. Their distance apart is adjustable to suit the eyes of the observer. One is fitted with a pair of micrometers at right angles capable of rotation in order to bring the horizontal and vertical wires parallel to the R-lines. The other is similarly fitted, with the exception that one horizontal micrometer is sufficient. The runs are adjusted on a scale.

The centres of the plates are separated to a sufficient distance by introducing in each microscope a pair of prisms of total reflection p (Fig. 4).

The micrometers might also be used in the position of the plates, giving more room for the screws and greater facility in the reading of their heads, and the plates themselves set further back, behind an additional lens, as in the Cambridge measuring machine recently described by Mr. Hincks (*Monthly Notices*, lxi. p. 444).

The zero wires form a frame fitting an R-square, as in Sir David Gill's machine used at the Cape Observatory (*Monthly Notices*, lix. p. 61).

For convenience the whole arrangement is tilted at an angle of 45°, and the light illuminating the plates reflected by mirrors *m* from a window at the back of the observer.

The setting of the plates may be effected by turning a micrometer to the inclination of the base by means of a graduated circle, and making both sets of R-lines agree in inclination and height with the micrometer wires. The second micrometer is then set by making its wires parallel to the vertical R-lines on either plate.

The vertical R-lines are combined by the microscopes, but the horizontal lines only when the distance between the centres of the pictures is equal to that between the microscope object glasses. In making a measurement, the plates are moved by the slow-motion screws on the slides of their carriers and of the stage until the zero square of one microscope fits a zero square of the corresponding plate and the zero wires of the other microscope coincide with a pair of vertical R-lines on the second plate. The points in the field of view may then be bisected without disturbing the zero settings.

The coordinates of a point on the plate are given by the direct readings of the micrometer heads added to the value of the R-line considered. The stereoscopic difference results from the difference of the x's on the two plates.

Range of the Method.—In practice, the range of the method is limited by the blurring of distant detail by light diffused in the atmosphere. This "aerial perspective" is reduced by the use of orthochromatic plates and an orange screen cutting off the rays of shorter wave-length which form the blue haze, but even then the effective range would probably not exceed some 5 miles, or 8 kilometres.

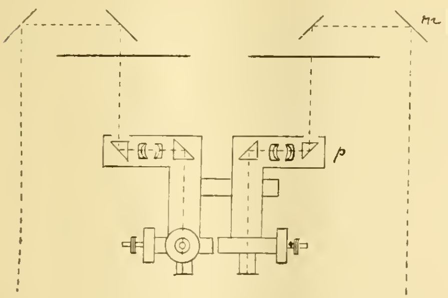

FIG. 4.

On the other hand, the difference in phase of the objects would prevent their ready combination at distances less than three to four times the length of the base. The view would then correspond with that of a model seen with the eyes at a distance of 10 inches from the nearer edge.

Let $2b$ be the length of the base and α the angle subtended by it at a distance y. Then:

$$y = b \cot \frac{\alpha}{2},$$

$$\frac{dy}{y} = -\frac{b}{y} \cdot \frac{d\alpha}{2\sin^2\frac{\alpha}{2}}$$

$$= -\frac{d\alpha}{\sin \alpha}.$$

Let 1/100th of an inch or 0·25 mm. be the admissible error on the plan, 8 kilometres the limiting value of y and $\Delta\alpha = 20''$. On the scale of the Canadian photographic surveys, 1/40000, the maximum error allowable will be 10 metres at 8 kilometres, or $\Delta y/y = 1/800$. Then $\alpha = 4° 27'$ and $2b = 620$ meters.

By increasing the base to 2 kilometres, a maximum possible accuracy at 8 kilometres of 1/2500 of the distance, or 3 metres, would be attained, but the area mapped would be reduced to a narrow strip.

With the base of 620 metres, the area mapped with a plate of diameter equal to the focal length of the lens would be contained between the limiting circles, at 8 and 2·5 kilometres, shown at *d* and *n* (Fig. 5), and would amount to 22 square kilometres on either side of the base, or more correctly to that portion not masked by the nearer topographical features.

The error in x will be due to that in y and that of the x-coordinate on the plate. We may write:

$$(\Delta x)^2 = \left(\frac{y}{f}\Delta l\right)^2 + \left(\frac{x}{y}\Delta y\right)^2.$$

With a lens of 150 mm. focal length and an error of ·025 mm. in the plate x's, the maximum error is, for the base and the scale of plan considered, 5 metres, or on the plan 0·12 mm.

The error in height is given by the same expression. At the maximum distance, the second term cannot exceed $(1/4\,\Delta y)^2$ if the difference in height between the base and the distant points does not exceed 2000 metres. In absolute amount the total error for points at extreme distances would be $\pm$ 2·75 metres.

The contour lines should then, in the case already considered, be accurate to 0·25 mm. on slopes greater than 15°, but the actual accuracy will be reduced to some extent by the uncertainty of the correction for refraction. This correction, combined with that for curvature, can be applied at sight from a small table with y-argument.

By reducing the base, pairs of photographs may be taken within a confined space, as when mapping hidden valleys. The method can also be combined to any extent with the ordinary methods of photographic surveying. It would be of particular advantage in the mapping of large areas of mountainous country.

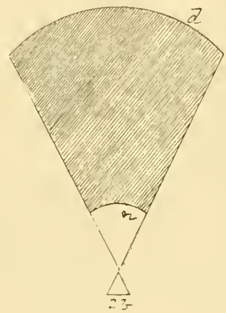

FIG. 5.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following examiners have been appointed in the Natural Science Schools:—Mr. William B. Croft, Pembroke College (physics), Dr. Alexander Scott (chemistry), Dr. Leonard E. Hill (animal physiology), Mr. John Watts, Balliol College (chemistry)—*vice* Mr. Elford, resigned.

THE 237th meeting of the Junior Scientific Club was held on May 29, in the museum. Mr. A. F. Walden, New College, demonstrated a new method of distinguishing between calcium and strontium. Mr. E. A. Cockayne, Balliol, exhibited a natterjack, and Mr. Lattey, Trinity, read a paper on the occurrence of natural gas in England.

MR. DAVID ROBERTSON, lecturer in electrical engineering at the Bradford Municipal Technical College and formerly assistant lecturer at the Glasgow and West of Scotland Technical College, has been appointed professor of electrical engineering at the Merchant Venturers' Technical College, Bristol.

THE annual exhibition of work from schools and classes of the School Board for London will be opened by Lord Reay on

June 18. A section will be devoted to scientific apparatus constructed by teachers and pupils. The Board, in including this section has in view the possibility that, by encouraging the construction of apparatus by its teachers and pupils, it may be possible to reduce the present heavy accounts for scientific apparatus and also that, at the same time, it may assist in familiarising the pupils with the practical use of apparatus. The sight of apparatus of a cheap and "home-made" character will be the means of encouraging the study of practical science at home.

ENCOURAGEMENT is being given to the study of natural history or nature-study in many districts. A programme has been sent to us of a series of Saturday afternoon rambles organised for the benefit of teachers by the Technical Instruction Committee of the Essex County Council. Conducted in the sympathetic spirit of the true student of animate nature, the excursions may be made a source of pleasure and profit to all who participate in them, but great care must be taken to prevent them from becoming expeditions of extermination. Prof. Miall points out this danger in a letter to the third number of the *Nature-Study Journal* published by the South-Eastern Agricultural College, Wye. The journal also contains short papers on uses of the balance, the metamorphosis of frogs, bees and flower shapes.

LORD ROSEBERY referred to the Education Bill in his address at Leeds on Friday last. He summed up the Bill by saying that "it discountenances efficiency in primary education, rewards inefficiency, starves secondary education, and ignores altogether the training of teachers." Education, he urged, is a national and Imperial duty, and its development should not be dependent upon local rates. The Bill provides that municipal authorities may apply the balance of the "whisky money," and may spend up to a twopenny rate in order to provide for the higher secondary and technical education so urgently needed in this country. This is not only inadequate in amount, but unsound in principle, and, remarked Lord Rosebery, "the putting of education on the rates is perhaps the surest method that the Government could have chosen for restraining the educational development of this country."

NEW regulations for secondary day schools have been issued by the Board of Education. The schools will be in two divisions—one containing what have hitherto been designated schools of science or organised science schools; and the other, secondary schools having courses in which science is given fair attention. The schools in Division A must provide a thorough and progressive course in science, together with the subjects of a general education. The obligatory subjects are mathematics, physics, chemistry, drawing and practical geometry; and not less than fifteen hours per week must be allotted to instruction in them, of which not more than five hours are to be given to mathematics. Practical work must be done in every science subject. On the completion of the elementary course, students may select physical, mechanical or biological courses, such as have been carried on for some time in schools of science. In Division B of secondary day schools, not less than nine hours a week must be given to science instruction in forms for which grants will be made. The instruction must be both theoretical and practical, and the laboratories must be suitably equipped for the subjects sanctioned.

THE executive committee of the National Association for the Promotion of Technical and Secondary Education adopted the following resolutions referring to the Government Education Bill at a meeting held on May 30:—(1) That this executive committee, while expressing no opinion on the more controversial aspects of the Education Bill relating to elementary education, regards it as essential to the interests of technical and secondary education, (*a*) that the fund available under the Local Taxation (Customs and Excise) Act, 1890, should be permanently appropriated by the Bill and devoted by the local authorities to the purposes of technical and secondary education; (*b*) that the areas of administrative control over technical and secondary education by local education authorities should, as provided by the Bill, continue to be the administrative counties and county boroughs or combinations of such areas. (2) The executive committee also considers it highly desirable, (*a*) that clauses 3 and 15 should be so amended as not to deprive any local authorities of the power they now possess to levy a penny rate for the purposes of technical and secondary education; (*b*) that the local authorities should be represented on the governing bodies of all institutions to which grants are made.

IT has already been announced that Mr. Alfred Mosely has arranged to send out to America two commissions of inquiry—one to study methods of education in their bearing on commercial and industrial efficiency, and the other industrial organisation and the problems of labour and capital. We learn from the *Times* that Mr. Mosely has just returned from the United States, where, in conjunction with President Butler, of Columbia University, he has settled the provisional itinerary of the educational commission. The exact date when this commission will start has not yet been decided. The programme arranged by President Butler seems to be of an exceedingly instructive and comprehensive character. Among the places to be visited are New York, with Columbia University, Auchmuty trade schools, the Educational Alliance, the University Settlement Society and the Normal College; New Haven, Conn., where Yale University will be inspected; Boston, with Harvard University and the Massachusetts Institute of Technology; Philadelphia, for the University, the Drexel Institute, the Manual Training Schools and the Commercial Museum; Baltimore, where the Johns Hopkins University and Hospital will be seen; Washington, for the Smithsonian Institution, National Museum and the Department of Agriculture; Pittsburgh, with the Carnegie Museum; Chicago, with the University, the School of Education, Prof. Dewey's University School and the Armour and Lewis Institutes; and Ithaca, N.Y., where Cornell University will be visited.

FOUR years ago an important gift was bestowed on the University of Paris, but it seems to have attracted little public attention. The Minister of War having decided to abandon three of the bastions constructed at the south frontier of the Parisian fortifications, generously placed them at the disposal of the University of Paris for the purpose of higher education. Each bastion represents about 3000 square metres of site. The council of the University determined to devote two of these to extending the facilities of the Faculty of Science and the third to the use of the Faculty of Medicine, and on these areas buildings suitable for the new installations required in connection with the above Faculties, which in the absence of a site cannot be erected in the centre of Paris, were to have been built. But though, with the intention of proceeding to erect the necessary buildings, the gift of the Minister of War was immediately accepted by the Faculties of Science and Medicine, funds voted for the purpose, and designs prepared by the architect of the Sorbonne, nothing has yet been done in the way of building. This delay is, it appears, the result of numerous objections which have been raised in different quarters. In a recent number of the *Revue générale des Sciences* these objections are answered in detail, and it is shown that it would be a great pity from the point of view of facilities for scientific research if the unhoped for chance of fine large laboratories on the outskirts of Paris was, even provisionally, abandoned.

SOCIETIES AND ACADEMIES.

CAMBRIDGE.

Philosophical Society, May 5.—Dr. J. Larmor, vice-president, in the chair. Regeneration in *Samia ailanthus*, by Mr. H. H. Brindley. With the object of ascertaining the degree of regeneration and how far it is uniform in the imago after injury to the larva in particular stadia and to particular extents, amputation experiments were made on the legs of this moth in larva. Owing to the large number of cases in which the imago did not emerge the results were somewhat limited, but sufficient instances were observed to suggest (*a*) that compared with Orthoptera and other non-pupating forms the results of injury are very variable, (*b*) that the earlier the instar injured the imaginal limb more closely approaches the normal in form and size, (*c*) there is no uniformity in the presence of the terminal claw apparatus without regard to the number of limb joints such as has been observed in Arachnids, Myriapods and several orders of non-pupating insects, and (*d*) that the length of time spent in pupa and the degree of injury to the larval limb seem not to influence the degree of regeneration. As regards (*b*) the results are in general accord with those of Newport on Vanessa and Chapman on Liparis, though not as regards (*c*) with Newport. The experimental evidence obtained also seems to confirm Gonin's opinion, based on anatomical

grounds, that the imaginal limb is a distinct structure from the larval limb during the instar preceding pupation.—On the unit of classification for systematic biology, a reply to Mr. Bernard, by Mr. J. Stanley Gardiner.—Remarks on Marconi's system of telegraphy, by Mr. H. M. Macdonald.—On trinodal quartics, by Mr. A. B. Basset.—On a definite integral, by Mr. T. J. I'A. Bromwich.—Reflection and transmission of light by a charged metal surface, by Mr. P. V. Bevan.—Note on a general numerical connection between the atomic weights, by Mr. C. A. Vincent. If a list of all the atomic weights in ascending order of magnitude be taken and the order in this list be called n, then the nth atomic weight, from $n=3$ to $n=60$, is given by the equation

$$W=(n+2)^{1\cdot 21}.$$

If the atomic weights are from Clarke's 1901 list with hydrogen as unit, then the greatest difference between the computed and determined value will not exceed 4 units, nor will the error ever be greater than 5 per cent.; in thirty-six cases the result will not be a unit wrong and in twenty cases will not be 1 per cent. wrong; the mean error for the whole fifty-eight elements considered is about 1·005, the mean percentage error about 1·6. By replacing $n+2$ of the above formula by N, and taking N as indicating the order in an augmented list of the elements, the formula may be made to embrace the whole of the seventy-seven elements now definitely known. This necessitates predicting an element between hydrogen and helium and one between helium and lithium. No other gaps are left until after samarium, when in order to complete the list it is necessary to assume elements in various places, making fifteen gaps in all. The thirteen gaps introduced after samarium are in general accord with those predicted by the periodic table.—On radioactive rain, by Mr. C. T. R. Wilson. As the experiments of Elster and Geitel and of Rutherford have shown, a negatively charged body exposed in the atmosphere becomes radioactive, apparently showing the presence of some radioactive substance in the atmosphere; it occurred to the author to test whether any of this radioactive substance is carried down in rain. Freshly fallen rain-water (less than 50 c.c. was generally used) was found when evaporated to dryness' to leave behind a radioactive residue. The radioactivity was detected by means of the increase in the ionisation of the air within a small vessel, of which the top, or, in other experiments, the bottom, was of thin aluminium or of gold-leaf, the other walls being of brass. The metal surface on which the rain had been evaporated was placed close up to the aluminium or gold-leaf, and the rate of movement of a small gold-leaf which served to measure the ionisation was observed (v. *Roy. Soc. Proc.*, vol. lxviii. p. 151). In many cases the radioactivity obtained from the rain was sufficient to increase the ionisation five- or six-fold. From the evaporation of distilled water, of tap-water or of rain-water which had stood for many hours no radioactivity was obtained. Like the induced radioactivity obtained on a negatively charged body, that derived from rain gradually dies away, falling to about half its initial value in the course of an hour.—On the increase in the electrical conductivity of air produced by its passage through water, by Prof. J. J. Thomson. In continuation of the experiments brought before the Society last term, the author investigated the effect produced on the conductivity of air by bubbling it through water. The air from a large gas-holder of about 350 litres capacity was bubbled vigorously through water by making the air in the vessel circulate through a water-pump; this treatment increased the conductivity of the air, and when the bubbling had been going on for some time the conductivity of the air was ten or twelve times the initial conductivity. When once the air has been put in this highly conducting state it stays in it for a very considerable time; a large part of the conductivity produced by the bubbling remains in the air forty-eight hours after the bubbling has ceased, nor does it disappear when an intense electric force is kept applied to the gas. The effect produced by the passage of the air through water is similar to that which would be produced if the bubbling produced a radioactive "emanation" similar in properties to those emitted by thorium and radium. The conducting gas can be passed from one vessel to another; it retains its conductivity after passing through a porous plug; passage through a long tube heated to redness destroys the conductivity; it takes, however, a very high temperature to do this, temperatures less than 300° or 400° C. seem to produce comparatively little effect; if the gas is passed very slowly through a long tube filled with beads moistened with sulphuric acid, the conductivity is destroyed; unless, however, the stream of gas is very slow, the air retains a good part of its conductivity in spite of the sulphuric acid. Another point of resemblance between the "emanation" from radioactive substances and a gas in this state is that if a strongly negatively electrified conductor be kept in the gas for some time, the conductor becomes radioactive.

DUBLIN.

Royal Irish Academy, May 26.—Dr. R. Atkinson, president, in the chair.—Prof. Grenville A. J. Cole read a paper on Composite Gneisses in Boylagh, West Donegal, in which he urged that the essential features of the foliation in the gneissoid granite from Ardara to Finntown were due to conditions of original flow, and not to subsequent dynamo-metamorphism. He attributed the darkened types of granite, with a specific gravity of about 2·74, to admixture of the pure aplitic intrusive rock (specific gravity about 2·59) and the already foliated schists. The foliation in the granite is commonly accompanied by numerous residual flecks of schist, and larger elongated inclusions occur which have retained the strike of the masses of which they once formed a part. Subsequent shearing has here and there produced mylonitic structures, but the granite was converted into a gneiss by its mode of intrusion, under mountain-building pressures, along the planes of separation of an altered sedimentary series. The gneisses of Boylagh are thus almost all of composite origin, and the foliated masses and limestone bands lying in the central granite of Donegal, and running with so persistent a N.E. and S.W. strike, represent the undissolved residue of an anticlinal mass composed originally of numerous parallel folds. The trend of these folds and of the granite axis points to their establishment in the Caledonian epoch of mountain-building. The later pegmatitic veins which cut them, and which are not affected by the folding, may, then, be of Devonian age.

PARIS.

Academy of Sciences, May 26.—M. Bouquet de la Grye in the chair.—The motor muscle employed in the production of positive work. The comparison with inanimate motors, from the point of view of the dissociation of the several constitutive elements of the energy expenditure, by M. A. Chauveau.—On the ethology of the larva of *Sciara medullaris*, by M. Alfred Giard. The biological history of the larvæ of Sciara is dominated and directed by the conditions of the humidity of the medium in which the organism is placed.—The synthesis of petroleum: contribution to the theory of formation of natural petroleum, by MM. Paul Sabatier and J. B. Senderens (p. 138).—On the rays of convergence of a double series, by M. Eugène Fabry.—On the general exponential representation and some of its applications, by M. L. Desaint.—On functions of complex variables, by M. D. Pompéiu.—The receiver in wireless telegraphy, by M. Édouard Branley. The receiver in common use in wireless telegraphy has a radioconductor containing a fine metallic powder. Owing to the numerous contacts, these tubes are sometimes a little variable in their behaviour, and in attempting to increase the regularity of working the author has recognised that a radioconductor of the type oxidised metal-polished metal is the best, as it not only possesses the required regularity of working, but is more sensitive than the ordinary type. A description and figure of the instrument that has been found to give the best results is given.—On the electric discharge in flames, by M. Jules Semenov. In electric discharge in flames it was found that the negative pole heats much more than the positive pole, the negative pole being the seat of a phenomenon of a reflux of material particles the direction of which appears to be independent of the relative position of the two poles.—On the temperature of the electric arc, by M. Ch. Féry. The optical pyrometer of Chatelier was modified by the introduction of a thin prism of absorbent glass for the production of the photometric equilibrium. The temperatures thus observed with prisms of red and green glass were compared directly with the readings of a platinum-rhodium platinum couple, the results being in very close agreement up to 1500° C., the highest temperature attainable with the couple. Within these limits the law of Wien was found to be verified, and these results were then extended to the case of the temperature of the electric arc. The value found, 3882° C., differs considerably from the value found by Chatelier, 4100° C., from which the conclusion is drawn that carbon does not behave at its boiling point as a perfectly black substance.—Fields of force of bipolar diffusion, by M. S. Leduc.—On the modifications brought about by self-

induction in some dissociation spectra, by M. A. de Gramont. A continuation of previous researches on the same subject. The changes in the spectra brought about by changes in the self-induction of the spark circuit are studied in the cases of arsenic, antimony, graphite, silicon, germanium and thallium.—The employment of urine in the development of the photographic plate, by M. R. A. Reiss. Urine has a slight reducing action upon the photographic plate and may replace water in the developing solutions.—On the temperature of maximum density and the electric conductivity of some solutions of barium bromide and iodide, and calcium chloride, bromide and iodide, by MM. L. V. de Coppet and W. Muller.—On some physical properties of hydrogen telluride, by MM. de Forcrand and Fonzes-Diacon. A mixture of hydrogen and hydrogen telluride was prepared by the action of acids upon aluminium telluride, and this mixture passed through tubes cooled to -55° C. Pure hydrogen telluride separated out in the solid state, allowing of correct determinations of its melting and boiling points and molecular volume.—The preparation and properties of the chloro-, bromo- and iodo-sulphobismuthites of copper, by M. Fernand Ducatte.—On the alkaline cobaltioxalates, by M. Copaux.—On the constitution of the ammoniacal copper salts, by M. Bouzat. From a study of the amounts of heat developed in the reaction between solutions of ammonia and copper salts the author concludes that the ammoniacal compounds of copper ought to be considered as salts of complex bases.—On *p*:*p*-dinitrohydrazobenzene, by MM. P. Freundler and L. Beranger.—On the thiosulphocarbamic esters derived from primary amines, by M. Marcel Delépine.—The electrical resistance of metallic sulphides, by M. J. Guinchant. The resistance of the sulphides of iron, tin and lead was measured at varying temperatures. The resistance was generally a linear function of the temperature up to 100° C. The resistance of lead sulphide increased with the temperature, that of the sulphides of tin and iron decreased. The sign of the temperature coefficient would appear to depend upon the magnitude of the specific resistance, or of the causes which determine it, and not upon accessory phenomena, such as electrolysis, which accompany the passage of the current. The differentiation of solids into electrolytes and non-electrolytes according to the sign of this coefficient would thus appear to be unjustifiable.—The synthesis of aldehydes of the fatty series with the aid of nitromethane, by MM. L. Bouveault and A. Wahl (see p. 137).—The mechanism of the chemical variations in the plant when under the influence of sodium nitrate, by MM. E. Charabot and A. Hébert. Sodium nitrate behaves like the chloride in favouring esterification and reducing the percentage of water.—The composition and volumetric estimation of sodium methylarsenate, by MM. Adrian and Trillat.—Growth and auto-intoxication, by M. Frederic Houssay.—On the formation of the egg, maturation and fertilisation of the oocyte in *Distomum hepaticum*, by M. L. F. Henneguy.—On a new gigantic Pyrosome, by MM. Jules Bonnier and Charles Perez.—The modes of action and nature of the secretions of a pathogenic microbe, by MM. Charrin and Guillemonat.—Contribution to the study of life in seeds, by M. L. Maquenne.—The volcanic rocks of Martinique, by M. A. Lacroix.—The biochemical action of extract of kidney on certain organic compounds, by M. E. Gérard. The aqueous extract of the kidney of the horse, from which all cellular elements have been removed, is capable of hydrolysing glycogen, guaiacol, oxaluric acid and lactose.—On a comparison of the action of cold and anæsthetics on nutrition and reproduction, by M. Raphael Dubois.—The disease of young dogs. Statistics of the vaccinations practised from May 15, 1901, to May 15, 1902, by M. C. Phisalix.—On the existence of lipase in the blood, by MM. Maurice Doyon and Albert Morel.—Experimental researches on the action of compression on the respiratory exchanges in man, by M. J. Tissot.

DIARY OF SOCIETIES.

THURSDAY, JUNE 5.

ROYAL SOCIETY, at 4.—Election of Fellows.—At 4.30.—On the Movements of the Flame in the Explosion of Gases: Prof. H. B. Dixon, F.R.S.—Contributions to the Study of Flicker. Paper II.: T. C. Porter.—Effects of Strain on the Crystalline Structure of Lead: J. C. W. Humfrey.—The Spectra of Potassium, Rubidium, and Cæsium, and their Mutual Relations: H. Ramage.—On Some Definite Integrals and a New Method of reducing a Function of Spherical Co-ordinates to a Series of Spherical Harmonics: Prof. A. Schuster.

CONTENTS.

THURSDAY, JUNE 12, 1902.

THE HISTORY OF THE MYTH-MAKING AGE.

The Ruling Races of Prehistoric Times in India, South-western Asia, and Southern Europe. By J. F. Hewitt. Vol. i. Pp. lxv + 627 (1894), 18*s.* Vol. ii. Pp. xxxv + 382 (1895), 12*s.* (Westminster: Constable and Co., Ltd.)

History and Chronology of the Myth-making Age. By J. F. Hewitt. Pp. xlviii + 682. (London: Parker and Co., 1901.) 15*s.* net.

THE object of the present short article is not so much to call the attention of the readers of NATURE to two works by Mr. J. F. Hewitt, late Commissioner of Chota Nagpore, who has devoted many years of hard work to the elucidation of the history of the ruling races of prehistoric times in India, south-western Asia, and southern Europe, as to mention some of the difficulties connected with the history and chronology of the myth-making age. To discuss at length and in detail the contents of the three volumes the titles of which appear at the head of this review would require several numbers of NATURE, or a whole volume, and while an attempt is here made to indicate the general line of his arguments and the trend of his opinions, the reader, if he wishes to become master of the subjects as treated by Mr. Hewitt, must read the works themselves. Mr. Hewitt brings to bear upon his studies a knowledge of several Indian dialects, and a general knowledge of what other investigators have written about subjects which are germane to his own; his observations and opinions have not been formed hastily, and every fair-minded reader will, after a perusal of his works, arrive at the conclusion that he is an honest, even if sometimes mistaken, seeker after facts, and that, so far as his knowledge will allow him to do so, he sets the truth before those who will take the trouble to read what he has written. The chief importance of his books, in the writer's opinion, is the proof which they afford of the little value of philology in arriving at any decision as to the religious views and practices of early nations; moreover, we cannot help wishing that when Mr. Hewitt was making his quotations he had taken the trouble to give the words and passages on which he bases his arguments in the languages in which they were originally written. We have no intention of finding fault or of making carping criticisms, but Orientalists other than experts in Indian languages would have felt much more comfortable if they could have seen before them the Babylonian, or Assyrian, or Egyptian forms of the words which he quotes. The answer to this objection is, of course, that the use of mixed Oriental types is a costly luxury to an author, and to many it will seem a sufficient one; meanwhile, let us thank Mr. Hewitt for what we have, and then proceed to consider generally the aim and scope of his work.

The older of the works before us is that which deals with the ruling races of prehistoric times in India, and consists of a series of eleven essays, six of which were published in 1894 and the remaining five in 1895. In a somewhat lengthy preface, Mr. Hewitt explains that he intended to call especial attention by means of them to the chronological data which can be obtained from "social laws and customs, mythic history and ritual," and to show how the leading epochs of civilisation succeeded one another in prehistoric times. In the first essay he describes how he was drawn into the line of study in 1863, when he went to Chota Nagpore as Deputy Commissioner, and how the system of indigenous Indian village communities spread thence through all the countries lying between it and north-west Germany. Mr. Hewitt next thought he had found that the clues to the history of early Hindu ritual given in the Rigveda and elsewhere could only be explained by comparison with data obtained from Accadian texts, and he apparently still thinks that Hindu and Accadian mythology developed on nearly identical lines, the Zend ritual being a common link between them. He also came to the conclusion that Egyptian religious and national history in the two stages of its growth can be traced to Indian and Accadian sources, and that it was impossible that the maritime commerce, whence the wealth was earned which made the Euphratean countries and Egypt rulers of the ancient world, could have been founded except by the Indian seaman. In the essays which follow he sets out the reasons, philological, religious, and historical, which have induced him to hold these views, and adduces a number of theories, many of an astronomical character, in support of the same. We must, however, at the very outset protest against the statement that the Egyptian religion, as such, can be traced to India, and we much doubt if Hindu mythology can be compared with Accadian mythology in any way. Thanks to the labours of men like Brugsch and Maspero, we know a little about the Egyptian religion and the gods of Egypt, and the more we know the more we find that the oldest gods of Egypt were indigenous, and that the religion of the earliest period was the very characteristic product of an indigenous race of north-east Africa. Whether Mr. Hewitt is right or we are, others must decide; but any comparison between the name of the Egyptian god Osiris (Às-âr) and the Accadian god Asar (or Asaru) is scientifically impossible, and when he says that Heru (or "Horus" as he spells it) was the equivalent of the Ashēra, "or rain pole of the Semites," and the "Tur or meridian pole of the Akkadians," we are obliged to disagree entirely with him. The Accadians appear to have had a god called Zu-ab or Apzu, who had something in common with the Egyptian Nu (not Nun, as Mr. Hewitt writes the name), but to say that both Accadians and Egyptians worshipped Nu is incorrect. In the first essay we also have a long dissertation about St. George, who, according to Mr. Hewitt, was:—

"the rain-god, the knight of the cross, for it was in the centre of the tortoise earth that the mountain of rain-god stood, and it is from the cross forming the ground plan of the tortoise, with the pole or mountain in the centre, that the Egyptian star of Horus was formed" (p. 17).

But in Egyptian mythology Horus had no special star, and the five-rayed star was the common symbol of stars and gods in general. If anything, St. George was a solar god, and all the details of his history go to prove

his identity, not with a rain-god, but with the sun-god Rā in Egypt and Marduk in Mesopotamia. We cannot follow Mr. Hewitt here in all his derivations, because it seems that he is influenced too much by the similarity of the sounds of roots and not by the probability of their relationship. Thus, on p. 27, he speaks of "Rāma, meaning 'the darkness' in Sanskrit and 'the heights' in Hebrew." The fact is that "Râma" does not mean "heights" in Hebrew, but *Râmâh* does mean "high"; even so, however, it is not in any way related to the Sanskrit Rāma, and the words Rāma and Râmâh must not be compared in this way. The second essay, which deals with the primitive village, is more interesting, and contains a number of original remarks which show that Mr. Hewitt has thought out the subject with care; but in the third we again touch serious philological difficulties. Mr. Hewitt has followed the speculations of many masters, and has in consequence made a good many mistakes. Thus, Isis was not a star-goddess originally, but her soul went to the star Sept, and the name Ȧst (Isis) has no connection with Accadian at all. In this, as in many other places, Mr. Hewitt has adopted Prof. Hommel's views, which are not generally accepted either by Assyriologists or Egyptologists. At this time of day it is little less than foolish to quote Lenormant's works on Accadian, for it is now well known that his skill in reading cuneiform of any sort was very small, and that his imagination and boldness of assertion were very great. On p. 292 we have an extraordinary set of equations, *e.g.* Tur, the pole = taurus = Syriac *tawrâ*, a bull = Hebrew *shur*, an ox = Tyre! In the fourth essay a number of astronomical myths are described, and Mr. Hewitt lays down the theory that the primitive year contained two seasons, that it was followed by one of three seasons, and that mankind eventually made use of a year of five seasons. He supports his theory by means of a large number of impossible philological comparisons, and says, among other remarkable things, that the constellation Leo

"was the Māsu or Moses, who, as the pillar of cloud and fire, led the star-worshippers to the top of Mount Nebo, consecrated to the planet Mercury, the great Nabi or prophet of the Semites" (p. 352).

We do not intend to weary the reader with further extracts from these essays, for the passages already quoted will explain Mr. Hewitt's methods, and serve to show how philology is made to run riot in them; the other remarks on the volumes generally we shall make after we have briefly described the contents of the work "History and Chronology of the Myth-making Age." The period of time which Mr. Hewitt discusses in this portly volume begins with the "first dawn of civilisation" and ends at the time when the sun entered Taurus at the vernal equinox between 4000 and 5000 B.C., his "pivot date" being B.C. 4200. About this time, he says, it ceased to be a universally observed national custom to record history in the form of historic myths (*sic*), and national history began to pass out of the mythic stage into that of annalistic chronicles recording the events of the reigns of kings and the deeds of individual heroes, statesmen and law-givers. It would be extremely interesting to know why B.C. 4200 was fixed upon as the pivot date, for there is reason to believe that the making of myths did not cease at that period. For all practical purposes Mr. Hewitt's book on the myth-making age is divided into three parts, which treat of the age of pole-star worship, the age of lunar-solar worship and the age of solar worship. These are followed by four appendices, which give a list of the Hindu stars, versions of the "House that Jack built," the legend of Ino and a dissertation on Melgareth. The section on pole-star worship treats of the year of two seasons and of five-day weeks, the year of three seasons and of five-day weeks, and the year of three seasons and of six-day weeks; the first of these years, Mr. Hewitt asserts, was measured by the movements of the Pleiades and the solstitial sun, the second by Orion, and the third by the eel-god. The second section treats of the epoch of the three-year cycle and of the nine-day weeks, of the year of the horse's head of eleven months and eleven-day weeks; and the third section discusses the fifteen-months year of the sun-god of the eight-rayed star and the eight-days week, the years of seven-day weeks and seventeen and thirteen months, the years of eighteen and twelve months, and of five- and ten-day weeks. In proof of the views which he holds on all these difficult subjects, Mr. Hewitt quotes largely from a great many works by authorities of varying trustworthiness; and he reproduces an appalling number of equations, a few of which, taken singly, are correct, but which, when looked at as a whole, are erroneous and misleading, and confuse the mind of the reader. Thus, on p. 29, we are told that Zeus is a form of the North Pole god Tan, that Tan = the Creto-Phœnician (*sic*) I-tan-os = the Accadian I-tan-a (*sic*), and the "tree mothers" of Accad, China, Germany and other countries are declared to have a common origin and to typify the same things. Statements of this kind are difficult to understand, at least when their writer intends the reader to believe that the ideas concerning the subjects of them were common to all peoples of antiquity, irrespective of the distance of their countries from each other. Moreover, they make it exceedingly difficult for any student to accept the generalisations which they express. There are, of course, many beliefs and conceptions which are common to all races of mankind, which are on the same level of civilisation, but there are large numbers of others which are not, and there are many which belong to a particular race, or to a people who live under peculiar geographical and physical circumstances. The cosmogony and theology of mountain races are different from those of the dwellers in plains, and those of the Semites differ from those of the Aryan nations. Another point is also to be considered in connection with the matter. Mr. Hewitt quotes authorities on the Chinese, Accadian, Sanskrit, Babylonian, Assyrian, Egyptian, Dravidian, and numbers of other languages, and without meaning to be disrespectful to him or to belittle his work, we must say that we have no belief in the philological omniscience which can decide about such abstruse questions as he formulates *and* answers. Men like Wellhausen and Kuenen have shown us what can be done in elucidating ancient religious beliefs by means of a knowledge of a group of *cognate languages*, but in our opinion no man is to be

trusted when he professes to deduce relationship of words, names and beliefs in Egyptian, which is an African (Hamitic) language, and in Babylonian, which is a Semitic language, and in Sanskrit, which is an Aryan language, and in Chinese and Accadian, which, whether they be related or not, have no relationship with any one of the other three. Mr. Hewitt, like Mr. John O'Neill, in his "Night of the Gods," has done a useful piece of work in collecting a mass of facts and theories, but they want sorting and arranging and winnowing, and especially condensing, before they can be used by the students of the various religions of antiquity. What is more important, moreover, is that the derivations of the words and names should be checked by experts in the various languages in which the books of the various religious systems are written, so that the student may be quite sure that no mistake has been made. Descending from generalities to particulars, we note that Mr. Hewitt speaks of the "Hittite" as if it were a known language; but it is not, and no inscription written in the script which is commonly called "Hittite" has yet been deciphered. It is true that "translations" of certain "Hittite" texts have been printed and published, but no trained philologist admits that they really represent the meaning of the texts from which they are alleged to have been made. Even the identity of the Hittites of the Bible has not yet been established, for whilst the Khatti of the Assyrian monuments may be identical with the Kheta of the Egyptian records, there is no evidence that either name is connected with the Hittites, or that the Hittites were related to the Kheta and Khatti. Similarly, Mr. Hewitt alludes to the Accadian language as if it too were known; but every student of comparative Semitic philology is well aware that the study of Accadian is so little advanced that certain eminent Assyriologists, no doubt erroneously, even now do not regard it as a language at all!

The general impression which a careful perusal of the book leaves on the mind is that Mr. Hewitt has proved too much; but be this as it may, it is our firm conviction that if he wishes his labour and learning to receive the study and recognition which they deserve, he must condense his statements and formulate his theses in such a way that the student who is not an Oriental philologist may be able to make up his mind what are the theories which Mr. Hewitt sets out to prove, and whether he has proved them or not. A sharp distinction should, of course, be made between theory and fact, but this Mr. Hewitt fails to make. In conclusion, we cannot help wishing that he had confined his attention exclusively to Indian languages, cosmogonies, and theologies, of which, obviously, he has had abundant opportunities of obtaining knowledge at first hand, and that he had not made such lengthy excursions into the domains of Chinese, Semitic, Egyptian and other studies of which he as obviously has no first-hand knowledge whatever, not even enough to distinguish good authorities from bad. He has, in fact, lost an excellent opportunity of writing a most interesting book on the early religious myths of India, and this we sincerely deplore. The indices to the volumes before us are remarkably comprehensive and good, and merit praise.

CYCLOPEDIA OF HORTICULTURE.

Cyclopedia of American Horticulture. By L. H. Bailey, assisted by Wilhelm Miller [and others]. In 4 vols. quarto. Pp. 2016. (London: Macmillan and Co., Ltd.; New York: the Macmillan Company, 1900 to 1902.) Price 21*s*. net each volume.

THERE are some books which gain the title "monumental" on the sheer score of size. The present work, which has recently been completed, has earned it, not only by its bulk, but by the quality of its contents, their freshness and diversity, and the originality of their treatment.

There are two ways of producing such a work as this, one by the free use of paste and scissors, a plan not to be despised if the compiler be at once honest and judicious, and the other wherein each article inserted is treated as a monograph. Facts are accumulated, contrasted, classified, so that in the result the reader has placed before him as complete a view of the whole subject as the limitations of space will allow. This is the plan that has been followed by Prof. Bailey and his 450 contributors and assistants. The Cyclopædia was to be new, "brand new from start to finish. The illustrations were to be newly made; the cultural suggestions written directly for the occasion from American experience and often presented from more than one point of view; few of the precedents of former cyclopædias to be followed; all matters to be worked up by experts and from sources as nearly as possible original." Considering all these things, the volumes constitute a real triumph of sagacity and organisation on the part of Prof. Bailey.

The matter, so far as we have tested it, is accurate, well set forth and in due proportion—a most difficult thing to secure when the work of so many contributors has to be correlated and adjusted. It is quite clear that a large share of the work, independently of planning and supervising the whole, has fallen to Prof. Bailey. Two things specially strike us in consulting the volumes, the one the way in which science, and especially evolutionary science, permeates the whole book, the other the way in which scientific knowledge has been set forth for the special benefit of commercial horticulture. In most or all books of the kind, botanical and physiological details are given, but here they seem expressly set forth for the benefit of those who make their living out of the land or the forcing-house. Science is not allowed to suffer in the least, but its application to commercial necessities is insisted on to a degree unknown in British horticulture. Prof. Bailey knows and caters for the requirements of the commercial cultivators in all or most of the States of the Union, and not the least valuable of his articles are those concerning the natural features and economic conditions of the several States and Territories.

So far as the plants are concerned, analytical keys are framed, so as to facilitate, by means of contrasting characters, the discovery of the name of each plant and of its salient features. The enormous and irksome labour involved in the construction of these keys can only be appreciated by those who have had to construct similar ones. An error the most trifling in itself may involve the

most serious consequences as regards the construction and the use of these tables.

In a work of such magnitude and diversity, it is futile to think that errors can have been completely avoided, but from frequent consultation of the earlier volumes we can testify to their remarkable freedom from printers' errors. We think a short account of each of the principal natural orders should have been given, and the space so allotted might have been saved, in part at least, by thus obviating the necessity of some amount of repetition in dealing with the several genera.

Prof. Bailey has availed himself of the resources of Cornell University, of the "Dictionary of Gardening" by Nicholson and of the numerous standard publications issued from Kew, and, amongst other sources of information, has consulted and compared some hundred or more catalogues of nurserymen. This latter procedure needs to be followed with the utmost caution and is one to which, perhaps, the omission of the genus Trochodendron is to be attributed. After all, the plants that have special interest for commercial purposes are few in number as compared with those which appeal primarily to the lover of plants or to the scientific botanist.

We might extend our notice of this book to a much greater length than the editor could allow space for. We can only add that the illustrations are very numerous, uniform in treatment, often very useful, but, on the whole, not equal in value to the text. Further, that although expressly compiled to meet American conditions, it will, with the necessary modifications, be of great value in all English-speaking countries.

THE MANUFACTURE OF SUBMARINE CABLES.

Les Câbles Sous-Marins. Fabrication. Par Alfred Gay. Pp. 203. (Paris: Gauthier Villars et Fils, n.d.)

THE author of this little book, as we are informed on the title-page, is an engineer in the employment of the Société industrielle des Téléphones, the leading French firm for the manufacture of submarine cables. The volume is one of a series appearing under the name of "Encyclopédie scientifique des Aide-memoire," edited by M. Léauté, who is also, we understand, connected with the Société industrielle des Téléphones. From the title of the series we gather that this publication is designed to serve as a pocket text-book for submarine cable engineers, though the style in which it is written and the absence of an index—a fatal omission for any work of reference—make it resemble a popular treatise on the subject of cable manufacture rather than a scientific handbook. One example will serve to justify this view. In his reference to the Wheatstone Bridge—the most usual form of testing the conductor resistance of a cable—the author makes no attempt to explain the theory of the test, but merely gives the connections and the formula for obtaining the result. A book on cable testing which evades an explanation of the *Pont de Wheatstone* is as great a curiosity as a treatise on Euclid which omits all reference to the *Pons Asinorum.*

One or two other points call for comment. With regard to the testing of the dielectric resistance, M. Gay observes that some physicists have expressed the opinion that, if sufficient time were allowed, the "spot" would return to zero and remain there. This could only happen in the case of a material which possessed an absolute dielectric resistance, and through which, consequently, no current could escape. Manufacturers have hitherto failed to discover this material. Further on, the author asks why the negative current is always the first to be applied to the cable, and answers his question by saying that he believes that there is no good reason for using one current in preference to the other. But M. Gay must know that, when testing a faulty cable under water, the chemical action of the zinc current tends to clean the fault and make it more apparent, while the copper current throws a deposit on the exposed surface and masks the fault. Thus the reason for using the zinc current first is to discover at once any fault that may exist.

Throughout his book the author pays too little attention to the question of capacity in connection with the manufacture of cables. On p. 14, in enumerating a long list of the conditions which a good dielectric must satisfy, he does not mention the desirability of a low capacity. In fact, on p. 107 he goes out of his way to lay stress on the superior importance of insulation tests to capacity tests, ignoring the fact that, *caeteris paribus*, the work to be got out of a cable depends on its capacity, its insulation being purely a secondary matter. Finally, on p. 145 M. Gay says that the engineer is not master of the capacity of a core, the dimensions of which are given him, as though the capacity could not be varied by the selection and mixture of the gutta-percha used, independently of its relative weight to the conductor.

For the rest, it may be sufficient to point out that, in connection with the table of coefficients, given on p. 85, for reducing the D.R. of the cable at the temperature at which it is tested to its equivalent at 75°, one must *divide* and not *multiply* (as instructed on pp. 147 and 149) by the coefficient given, for the D.R. at 75° is, of course, less than at a lower temperature and more than at a higher temperature. With regard to the brazing of a joint, M. Gay would find it difficult to scarf the two ends of the conductor, if he omits, as he does in the directions on p. 173, to solder them first.

Enough has been said to show that the book is not likely to prove of great value as a work of reference for cable engineers. But as a popular treatise on a process of manufacture of which the public knows little, and may like to know more, it deserves very favourable notice. The chapter on the composition and properties of gutta-percha is specially good, and on pp. 90 and 91 the author sums up very clearly and succinctly the reasons for the various conditions which specifications require the dielectric to satisfy.

"Voici, en deux mots, sur quels motifs est basée l'introduction de chacune de ces règles : on impose une limite inférieure d'isolement pour se garantir contre les défauts de fabrication ; on impose une limite supérieure d'isolement pour empêcher l'emploi des guttas très résineuses qui, en général, s'altèrent vite avec le temps ; on impose un résidu maximum dans le chloroforme ou le toluène pour s'assurer que le mélange a été bien nettoyé

et qu'il ne contient plus une proportion trop grande des matières étrangères ; on impose enfin un résidu minimum dans l'alcool bouillant ou, si l'on veut, un résidu maximum après décantation et évaporation du liquide ayant servi aux expériences pour obliger le fabricant à faire usage de lots contenant une proportion suffisante de gutta pure."

OUR BOOK SHELF.

Some Thoughts on the Principles of Local Treatment in Diseases of the Upper Air Passages. By Sir Felix Semon, M.D., F.R.C.P. Pp. 115 ; with Appendix pp. 130. (London : Macmillan and Co., Ltd.) Price 2*s.* 6*d.* net.

THIS little volume, reprinted from the *British Medical Journal*, consists of two lectures delivered in November, 1901, at the Medical Graduates' College and Polyclinic ; and there is an appendix consisting of two letters dealing with the controversy aroused by the publication of these lectures.

The book is evidently intended for the medical profession only, the object of the distinguished author being two-fold, that is to say, it is a serious protest against "operative intemperance" and an attempt to lay down some simple principles for the treatment of diseases of the upper air passages.

Such a protest from within the profession against "the lust of operation"—perhaps a euphemism for something still more discreditable—has long been needed, and will doubtless require periodical repetition.

For the craze for specialists for everything (even "for a child of 6 months old") has recruited the ranks of specialism with many undesirables, possessed of the minimum of really special knowledge, except such as is generally associated with one's conception of the pachydermatous and pushing commercial traveller.

The author, perhaps wisely, confines himself to the less offensive expressions, "lust of operation," "operative intemperance"—charges from which he, with everyone else, wholly exonerates all honourable members of the profession possessed of judgment and a proper sense of responsibility.

Coming to questions of treatment, the author divides the symptoms and signs arising in pathological conditions of the upper air passages into five categories :—(1) Affections of a purely local character. (2) Local manifestations of general systemic diseases. (3) Local manifestations in nose and throat dependent upon local diseases in correlated areas. (4) Affections of the upper air passages supposed to exercise direct or reflex influence upon other organs and parts of the body. (5) Local symptoms and sensations of obscure origin.

In conclusion, some observations are made on the necessity of a proper proportion being observed between the gravity of the disease and that of the interference, so as "to make the punishment fit the crime."

In admirably clear and concise language, the diseases included in the foregoing subdivisions are specified, and a surprising amount of detailed treatment, of the utmost value, given in the subsequent pages, for many of these conditions, *e.g.* the various stages of tuberculous laryngitis.

In addition, sundry more or less fashionable methods of treatment, such as breathing exercises, and catch phrases, such as "nasal insufficiency," are subjected to the most searching criticism ; whilst the dangers of ignorant "specialism" are fully exposed by a series of cases which has come under the direct observation of the author.

We congratulate the writer of these lectures, believing that he has done excellent service to his profession and to the public generally ; and we confidently recommend the volume both to the up-to-date general practitioner and to the specialist, whether broad- or narrow-gauged.

H. C.

Flora der ostfriesischen Inseln. By Dr. Fr. Buchenau. Fourth edition. Pp. iv + 213. (Leipzig : Wilhelm Engelmann, 1901.)

IN order to incorporate the results of the systematic examination of the mosses, hepatics and lichens of the East Friesian Islands, Dr. Buchenau has brought out a fourth edition of his flora. The previous edition included the descriptive text of the phanerogams and pteridophytes and a highly interesting ecological account of the types of vegetation. A comparison of the flora of the islands and of the mainland brings out some curious points of difference. On this account the author rescinds his former opinion that the plants had travelled over from the continent ; more probably, he suggests, the insular vegetation represents the remains of an ancient *diluvial* flora. No changes are made in the previous issue, the new edition consisting in the addition of some extra pages, which contain a list, without diagnoses, of the Muscineæ and Lichenes and an appendix giving corrections and addenda. Amongst the mosses it is interesting to find recorded a group of Bryums, represented by *Bryum calophyllum*, which are found locally in this country on sandhills near the mouths of certain rivers. The fungi of the islands are now being worked by Herr E. Lemmermann, and his results will be included in a future issue.

Occultations of Stars and Solar Eclipses. By Francis Cranmer Penrose. Second edition. Pp. viii + 36. (London: Macmillan and Co., Ltd, 1902.) Price 12*s.* 6*d.* net.

THE first edition of this book was published in the year 1869, but in the present issue Mr. Penrose has not only simplified and condensed the work contained in it, but has extended it in that portion which relates chiefly to total solar eclipses. Most of us are familiar with the importance of determining one's position on the earth's surface, especially when on the ocean or on land far removed from the privileges of civilisation, and any attempt, either by a graphical or computational process, to facilitate this object is very welcome both to navigators and travellers. In this book Mr. Penrose treats the methods of predicting such phenomena as occultations of stars and eclipses of the sun by graphical construction, and he adds more rigorous methods of reduction for the accurate calculation of longitude. The very full explanation of the principle involved, the details of the working out of each case in point, the tables to facilitate the necessary computations, and the skeleton forms for actual practice, will all be found sufficiently clear to enable the worker to understand the practical use of the method.

Algebra. Part ii. By H. G. Willis. Pp. liii + 375. Rivington's Junior Mathematics. (London : Rivingtons, 1902.) Price 1*s.* 4*d.*

IN these pages we have a collection of algebraical exercises arranged in a progressive order of difficulty and suitable for elementary classes. The compiler has divided the examples in the following way : collection in groups suitable for lessons of about an hour, more advanced questions at end of each group ; exercises grouped in series of twenty-six, furnishing two lessons per week for a term ; two sets of parallel series either for alternate terms or for more lessons than in one series ; oral questions at the beginning of each exercise. The scope of the questions carries the exercises up as far as the progressions. The book should prove useful to teachers who require graduated courses ; answers to all the questions are given at the end.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Earthquake in Guatemala.

THOUGH I have been a subscriber and devoted reader of NATURE for about twenty years, I have not hitherto troubled you with any communications. Now I think it will interest you to obtain some data about a very disastrous earthquake which recently shook nearly the whole of the republic of Guatemala and the neighbouring countries, destroying many towns and causing immense loss of property and of many lives.

At 8.25 p.m. of April 18 an earthquake of more than thirty seconds duration affected a large part of Guatemala, eastern Chiapas and western Salvador and Honduras. The intensity of the movement was greatest in western Guatemala, where the second and richest city of the country, Quezaltenango, was completely destroyed, with the loss of about 500 lives. Completely ruined also were Sololá, San Marcos and its sister town San Pedro Sacatepequez (more than 200 lives being lost), and the same happened to Retalhuleu and Mazatenango, important towns on the Pacific coast-plain, to the south of Quezaltenango. The places before mentioned are situated on the highlands, a little to the north of the great volcanoes.

Earthquake, 8.25 p.m., April 18.

Limits of Guatemala.

Region of greatest intensity.

Region where buildings were destroyed.

+ Quezaltenango. Towns completely destroyed.

● Escuintla. Towns which suffered damage.

Region from which notices about the earthquake have reached me.

⟡ Nenton. Places where the shock was felt distinctly.

From Chiapas there is only one report about Tapachula, and from Honduras about Comayagua. It is not possible to say how far to the east and to the west the movement was felt.

Besides the cities named, nearly every town and hamlet in the Departamentos of San Marcos, Quezaltenango, Retalhuleu, Suchitepequez and several in Chimaltenango are ruined, and perhaps every one of the many important coffee- and sugar-plantations in the western coast-region has had its buildings, machinery and the aqueducts ruined. The total number of lives lost may be about 800 to 900.

At the port of Ocos, only three houses remained standing and the big landing-pier was broken near the land.

In the city of Guatemala most of the churches and some houses sustained slight damages; the same happened in Antigua (Guatemala). Escuintla and Amatitlan suffered considerably.

The railways between Retalhuleu and the port of Champerico, and the one between Ocos and Coatepec were interrupted by the falling of bridges and damage to the road. The railway between Guatemala and the port of San José remained unaffected and intact.

In the eastern portions of Guatemala the shock was only weak. I was at the time on my plantation "Germania," and did not feel anything at all.

Until May 5 earthquakes of small intensity were still frequent from the city of Guatemala to the west.

A commission of engineers has been sent by the Government to Quezaltenango and San Marcos, to select new places for the rebuilding of these towns.

During the night of April 11–12 a severe thunderstorm did considerable damage to houses and other property at San Salvador, the capital of the republic of El Salvador, and at 7.25 p.m. on April 16 a powder explosion blew up the military barracks at Managua, the capital of Nicaragua, destroying a number of houses and killing many people. I mention this because later on these events might get mixed up with the earthquake.

EDWIN ROCKSTROH.

Gualan (Guatemala), May 7.

The Vibration of the Violin.

I HAVE been taken to task for saying, in my little book on the violin, that the vibrations of the wood of the instrument "reinforce the tones of the string." Perhaps some readers of NATURE may be able to point out whether I am guilty of an incorrect or merely unconventional statement.

Briefly, I use the word "reinforce" in the fullest sense, or rather senses, of the term. There is, I take it, (1) a reinforcement of the tones of the string itself by *resonance*; and (2) a reinforcement (in the sense in which an army is reinforced by a regiment or battalion) consisting of the tones contributed by the vibrations of the pine and sycamore.

The reinforcement of the sound of a brass band by cymbals would seem to supply another and more direct analogy.

The tones of the string are no doubt by themselves very feeble, but not unimportant when reinforced by resonance. If in the case of the violin we substitute for the ordinary gut string a string of, say, silk, we distinguish a slight, but quite perceptible, difference in the *timbre* of the instrument; but this difference is not a measure of the intensities of the particular tones to which the difference is due.

If I is the intensity of the fundamental tones of the two strings, Σi the sum of the intensities of the overtones of the gut string, and $\Sigma i'$ the sum of the intensities of the overtones of the silk string, then what we distinguish in the consonant note of the instrument is

$$(I + \Sigma i) - (I + \Sigma i') \\ = \Sigma i - \Sigma i';$$

but we form no idea as to the absolute values of I, Σi and $\Sigma i'$. We cannot, in fact, say in what proportion they contribute to the intensity of the consonant note of the instrument.

(The difference observed in the *timbre* of the gut and silk strings is not, of course, necessarily due only to a difference of

intensity in their overtones. There may be a difference in number, but this does not appear to affect the question of whether the tones of the string form an appreciable part of the consonant note of the violin.)

If a vibrating tuning-fork is placed in contact with the wood of a violin, the instrument reinforces the tone of the fork; but the vibrations of the wood are here much less powerful than in the case of the string, and consequently the instrument only feebly asserts its own *timbre*. A very ordinary violin will reinforce the tone of a fork almost as perfectly as a masterpiece of Cremona.

I therefore take it that the reinforcement of the tone of the fork is chiefly the result of resonance, and that the intensity of the tone of the violin is due to the reinforcement of the tones of the string itself by resonance, *plus* the reinforcement contributed by the tones of the pine and sycamore, and that the latter determine the *timbre* of the instrument.

The tones of the pine and sycamore are also reinforced by resonance, in the same way as those of the string.

June 2. W. B. COVENTRY.

The "Armorl" Electro-Capillary Relay.

ON p. 129 of vol. lxv. of NATURE, a description is given of an electro-capillary relay. The writer states that the actual apparatus was not seen by him, "but only a working model." It would be highly interesting to know the exact meaning of this expression. Does it mean a model which *will work*, or only a model in which the different parts of the apparatus are shown, say, in wood or cork or any other substance. In the illustration, the mercury when acted on electrically is shown as moving the lever of a relay. A well-made capillary electrometer is highly sensitive to a small change of potential, but the movement of the mercury column is so minute that it is very difficult to see how any lever of a relay could possibly be worked by means of its movement. Some further information about the "Armorl" relay would, I feel sure, be acceptable to many, showing the potential difference required to cause the mercury to work the lever *k*, and also the approximate E.M.F. set up at, say, ten miles from the sending station of a wireless telegraphic system. J.-S.

Prehistoric Pygmies in Silesia.

UNDER the above heading, Prof. G. Thilenius, of the University of Breslau, has recently (*Globus*, Bd. lxxxi. No. 17) made an important contribution to European ethnology. His deductions result from an examination of a quantity of osseous remains preserved in the Museum of Silesian Antiquities at Breslau, consisting of four groups obtained at different sites in the region between Breslau and the Zobten. They are, unfortunately, very fragmentary; but it has been ascertained that they are the remains of a number of persons of both sexes, all adult and all of very short stature. The mean height of one group is about 4 feet 8 inches (1·429 m.), of two others about 4 feet 11 inches (1·496 m.; 1·506 m.), and of the fourth about 5 feet (1·523 m.). With these Prof. Thilenius compares the remains of the Swiss pygmies described by Prof. Kollmann, of Basel, who estimates their height as ranging between 4 feet 5½ inches (1·355 m.) and 4 feet 11 inches (1·499 m.), and comparison is also made with the similar remains found at Egisheim (in Lower Alsace, near Colmar), which belonged, according to Herr Gutmann, to people whose stature ranged from about 3 feet 11 inches (1·200 m.) to something under 5 feet (1·520 m.). Further, the museum at Worms furnishes the remains of an individual of the estimated height of 4 feet 9 inches (1·445 m.). In all these cases, the bones show no trace of any pathological degeneration, and the consequent inference is that they represent a special race of low-statured men, or dwarfs. Profs. Kollmann and Thilenius seem to prefer the term "pygmy" as most appropriate in denoting a special *race*, "dwarf" (*Zwerg*) being regarded as applicable to abnormal specimens of a race of ordinary size. Most writers, however, make no such distinction; and, indeed, "pygmy" is far from being strictly accurate when applied to people of 4 or 5 feet in height. Prof. Windle states that a people may be described as "pygmy" in which the average male stature does not exceed 1·450 m. (4 feet 9 inches).

Prof. Thilenius gives a wide range for the period in which those little people lived. While those of the Rhine valley are placed far back in time, some of the Silesian dwarfs are assumed to have been contemporaneous with the Romans and the Slavs, the most recent being placed at about a thousand years ago. But, before arriving at anything like a final conclusion on any of the questions relating to the mid-European pygmies, Prof. Thilenius desires a much greater acccumulation of evidence in the shape of skeletal remains, and there is good reason to hope that this will be forthcoming in due time. Most of our information on the subject has been obtained within recent years, and fresh evidence can hardly fail to present itself to investigators in the future. DAVID MACRITCHIE.

Flames from Mud on a Sea-Shore.

WE should like to draw your attention to the following spectacle which some of us witnessed on the sea-shore at Blundellsands on Thursday evening, June 5, at about eight o'clock.

The evening was dull and grey, a strong north-westerly wind was blowing in from the sea and the tide was flowing in. In the distance we first saw smoke with frequent jets of fire bursting forth from the mud of a shallow channel. Drawing near, we perceived a strong sulphurous odour, and saw little flames of fire and heard a hissing sound as though a large quantity of phosphorus was being ignited. It was impossible to detect anything which caused the fire, only the water where the flames appeared had particles of a bluish hue floating on the surface. The area over which the tiny flames kept bursting forth was about 40 yards.

A gentleman present stirred up the mud with his walking-stick, and immediately large yellow flames nearly 2 feet in length and breadth burst forth. The phenomenon lasted some time, until the tide covered the part and quenched the fire. As we returned from our walk the atmosphere was impregnated with a strong odour of sulphur. An old resident of Blundellsands, who also witnessed the sight, said he had never before seen anything of a similar nature. H. T. DIXON.

9 Agnes Road, Blundellsands, near Liverpool, June 8.

Cuckoo's Egg Thrown out of Bunting's Nest.

ON the morning of May 25 I found a nest of the reed bunting (*Emberiza schoeniclus*) with a cuckoo's egg in it besides three eggs of the bunting itself. When I took some friends to see it two or three hours later, the hen bird was sitting on the three eggs, but the cuckoo's egg was lying smashed outside the nest. It is impossible that any person could have broken it, for there were no traces of bootmarks in the soft mud on the side of the dyke where the nest was, besides it being very unlikely for anyone to have passed the spot during the short time I was away. It would interest me to know if any of your readers are acquainted with cases of small birds pitching the cuckoo's egg out of the nest instead of hatching it in the orthodox style.

Higham, May 27. T. G.

VOLCANIC ERUPTIONS IN THE WEST INDIES.

IN the notes already published relating to the disasters which so recently overwhelmed Martinique and St. Vincent, reference has twice been made to the possible connection between seismic efforts and displays of volcanic activity. In connection with this, it has been suggested that had the sudden movements which on April 19 shattered cities in Guatemala been postponed, Mont Pelée and La Soufrière might still have been quiescent. By this it is not intended to convey the idea that if we take earthquakes generally and compare the registers of the same with the registers of volcanic eruptions we shall recognise any direct connection between the two. In Japan there are annually at least 1000 distinct earth shakings, but years may pass without the record of a volcanic eruption. Mount Fuji in that country has remained quiescent for the last 195 years, during which period it has been shaken at least 15,000 times, but in spite of this repeated aggravation the *mons excelsus et singularis* of Dai Nippon still watches peacefully over thirteen provinces round its base.

Like many other mountains in the world, if we may rely upon the records of its past history, it is yet engaged in raising steam, and when by this process the volcanic strain has sufficiently increased, some unusually large relief in seismic strain—even at a distance—may be the ultimate cause of a renewal of its activity. Volcanoes, like mines, require to be charged before they can be exploded, and the final cause of such explosions seems at times to be connected with bodily movements of their foundations, which movements may originate locally or be the *propter hoc* of corresponding disturbances originating at a distance. The shiverings which constitute local earthquakes, which are so frequent throughout the world, play but little part in these violent awakenings, and the giants sleep whilst humanity may be terrified.

To see how far such a view is sustained let us turn to the volcanic history of the West Indies. First of all attention may be directed to the fact that the volcanic activity of these islands is confined to the Lesser Antilles, from St. Martin in the north to Grenada in the south. In the larger islands, which run approximately east and west, like Cuba, Jamaica, Dominica and Puerto Rico, although there are volcanic rocks and hot springs, volcanoes proper do not exist. What we have to deal with are the peaks of "Antillia," now represented by a suboceanic ridge about 500 miles in length.

The following notes, derived from Fuchs' "Vulcane und Erdbeben" and other sources, may be taken as a summary of what is generally known respecting the vulcanicity of these outcrops. Although it is imperfect, yet it may suffice to illustrate the hypothesis that world-shaking earthquakes may be closely followed by volcanic outbursts.

Grenada.—The island is practically built up of two mountains which are joined together. The crater of Grand Etang is filled with water. Morne Rouge is built of ashes. The greatest height is 2749 feet. It contains hot chalybeate and sulphurous springs.

St. Vincent.—In 1718, on the night between March 6 and 7, a piece of land rose from the sea and then sank. There was a furious hurricane on April 24, and Morne Garou (La Soufrière) erupted. From 1718 to 1812 this mountain was quiescent, but in the latter year it erupted, changed the form of its crater, and its ashes fell in Barbados. The last violent eruption was on May 7, 1902. The intervals between eruptions have, therefore, been ninety-four and ninety years.

St. Lucia.—Qualibou, 1800 feet. At present this is in the solfatara stage. In the large crater there are small lakes, and sulphurous gas and steam escapes. It erupted in 1766. The highest peak is 2117 feet.

Martinique.—Mont Pelée, 4438 feet. It erupted at the end of the eighteenth century, on August 5, 1851, and lastly on May 8, 1902.

Dominica.—Here there are many solfataras. The highest peak is 4747 feet.

Guadeloupe.—The "Grand Terre," or the eastern side of the island, is not volcanic. Soufrière de Guadeloupe (4869 feet) erupted in 1778, 1797, February 1802, 1812 and 1836.

Montserrat.—The Soufrière is volcanic. On November 29, 1896, 20 inches of rain fell, and this was followed by many small earthquakes. For forty years before there had been but few noticeable shocks. Since the rainfall the springs give off more gas, and silver is blackened three miles away.

Nevis.—Sulphurous vapour escapes from the crater.

St. Christopher (St. Kitts).—Mount Misère erupted in 1692. At present there is a lake in the crater.

St. Eustatius.—The volcano is apparently extinct and covered with vegetation.

The eruptions we have to consider are therefore those of the years 1692, 1718, 1766, 1797, 1802, 1812 (two), 1836, 1851 and 1902 (two).

We will now compare these with seismic disturbances of which more detailed accounts are to be found in Mallet's Catalogues of Earthquakes, published in the Reports of the British Association 1852–1854, and in Lyell's "Principles of Geology."

1692.—June 7, between 11 a.m. and noon, Port Royal in Jamaica was destroyed. A piece of land of more than 1000 acres sank, carrying with it buildings and their inhabitants beneath the sea. There was great disturbance in the ocean, and houses throughout the island were shaken down. Mountains were shattered and a lake created. This was accompanied by the eruption of St. Kitts.

1718.—As already stated, this eruption in St. Vincent was accompanied by a "very violent" earthquake.

1766.—March 9, Island of Antigua, a violent shock. March 17, Island of Grenada, a violent shock. June 11 (midnight), Jamaica, especially at Port Royal, also at Cuba. In Jamaica a violent shock lasting one and a-half minutes. In Cuba it lasted seven minutes, and the shocks recurred up to August 1. July (middle of month, during the night), Ste. Marie, S. America, very violent shocks, followed by slighter ones every day up to July 21. August 13 (10 p.m.), Island of Martinique, an earthquake during a terrible hurricane. August (towards end of month), Island of Martinique, another and very violent shock. August 18, Guadeloupe. August (end of month), Cuba, an earthquake, City of St. Jago overturned. October 6, Island of St. Eustaehe, an earthquake accompanied by a hurricane. Very violent shocks. In the territory of Caraccas they recurred hourly (probably only at first) for fourteen months up to the end of 1767. According to tradition, the shocks were simple horizontal oscillations. At Surinam there were two other violent shocks felt besides the one here mentioned, viz on the 24th at midnight and on the 27th at 7 a.m. October 21, 3 a.m., Cumana and Caraccas in New Granada, S. America; also Island of Trinidad; also Surinam and all N.E. portion of S. America. The whole of the city of Cumana was ruined. Eruptions of sulphurous water frequently occurred, especially about Casanay, two leagues east of Coriaco. The inhabitants lived in the streets for the two years 1766–67. The Indians celebrated by feasts the approaching destruction and subsequent regeneration of the world. During these shocks a little island in the Orinoco sank and disappeared beneath the waters, and in many places disturbances of the surface were produced. The first and third of the shocks at Surinam were attended with subterranean noise, as were the shocks at the mission station of Encaramado. December 12, Martinique, a slight shock.

1797.—February 4, 7.45 a.m. On this date there was a destructive earthquake in Quito, in which 40,000 lives were lost. A great extent of country was shaken, and the ground about Tanguragua opened into enormous clefts, from which water and stinking mud (moya) issued. The mountain itself remained quiet, but the smoke from Pacto, seventy-five leagues distant, disappeared suddenly.

About this time a series of shocks began in the Lesser Antilles, and these did not cease for eight months, until the eruption of the volcano in Guadeloupe on September 27 "put an end to them."

1802.—On February 2 there was a "severe shock" in Antigua, whilst in Guadeloupe there were vibratory shocks accompanied by an eruption. Shocks were felt in the west Indian islands during February and March.

1812.—On March 26 of this year Caraccas was utterly ruined, and 10,000 of its inhabitants perished. Shocks continued until April 5. The waters of Lake Maracaybo were lowered, and Mount Silla is said to have lost 300 to 360 feet of its height by subsidence. On April 24 St. Vincent erupted, the noise of which was heard as far as Caraccas. Preceding this eruption, in St. Vincent and in the West Indian islands there had been very many shocks. In St. Vincent more than 200 had been noted. Another tremendous earth disturbance, took place before this eruption commenced on November 16, 1811, in the valley of the Mississippi, Ohio and Kansas. The ground was raised or lowered, and about New Madrid shocks occurred almost hourly for months and continued until the date of the Caraccas earthquake.

The eruptions in St. Vincent and Guadeloupe appear to have been closely associated with two unusually large seismic disturbances on the neighbouring American Continent.

1835.—On February 20 an earthquake was felt for nearly 1000 miles along the coast of Chili. Many towns were destroyed and the coast was elevated from 1 to 10 feet. Up to March 4 300 shocks were counted. A submarine volcano broke out near Bacalao Head, and the Andes for a distance of 1300 miles were before and after the convulsion in an unusual state of activity. In November of this year Conception was severely

shaken, and on the same day Osorno, at a distance of 400 miles, renewed its activity. "These facts," says Lyell, "prove not only the connection of earthquakes with volcanic eruptions in this region, but also the vast extent of the subterranean areas over which the disturbing cause acts simultaneously." In 1836, on June 22 (or May 22-23) different places in Central America were shaken, and this was accompanied by the eruption of a volcano east of Omoa. In this year there was an eruption in Guadeloupe.

Without continuing these extracts further, it seems that the sequence of events which has recently taken place since the catastrophe in Guatemala on April 19 is but a repetition of very similar sequences which have taken place in the same quarter of the globe during the past two hundred years. The Antillean range is apparently one that is extremely susceptible to seismic disturbances originating at a distance, and that it may be so is suggested by its recent geological history. According to Dr. J. W. Gregory, when the Isthmus of Panama was submerged it is possible that "Antillia" existed connecting North and South America, and the Caribbean Sea was then a gulf of the Pacific. In Lower or Middle Miocene times this was submerged, and abyssal oozes were deposited which are now raised in the Barbados to a height of 1095 feet above sea level. The magnitude of these movements and their rapidity, which has often been referred to by the opponents to the theory of the permanence of continental masses and oceanic basins, indicate that we have in the Antillean ridge a line of weakness characterised by unusual instability, and it is in all probability this instability which renders the Windward Islands so responsive to hypogenic changes in the neighbouring continent.

Seismic Disturbances.

The earthquake recorded at Shide on May 8, commencing at 2h. 49·5m. a.m., was also recorded at Kew, Bidston, Edinburgh and Potsdam. The times of maximum motion at Shide, Kew and Bidston were 3h. 21·7m., 3h. 18·2m. and 3h. 23m.

The time taken for this movement to travel from the West Indies to Kew would be about 37 minutes. The local time of origin in the West Indies would therefore be May 7, 10.37 p.m. This time, calculated from other data, was given in NATURE, May 29, p. 111, as being about 10.33 p.m. Two other seismograms relating to this disturbance as recorded at Shide have not yet been examined. When this is done more certainty respecting this time is to be expected.

Assuming the clock in St. Pierre, which stopped at 11.50 (or 7.50 a.m. local time) to have been correct, this earthquake took place about twelve hours before that event occurred.

It is curious that although this earthquake was noted in Potsdam it does not appear to have reached Laibach and certain other European stations.

At Shide a slight earthquake was recorded on May 25 *about* 5.28 p.m., and a second shock at *about* 4.20 next morning. They are both small, and the relationship between the preliminary tremors and maximum motion is too ill defined to state definitely the distance at which they originated. J. MILNE.

RECORDS AND RESULTS OF RECENT ERUPTIONS.

SEVERAL interesting observations and records connected with volcanic eruptions and earthquakes have come under our notice during the past week. As has already been remarked, the exact cause of the sudden destruction of the inhabitants of Martinique after the eruption of Mont Pelée is a little difficult to determine. Witnesses who were on the *Roddam* in the bay of St. Pierre at the time of the disaster on May 8, state that when the eruption occurred the vessel was struck with such force by the material ejected that she was nearly capsized and seemed to be enveloped in "a whirlwind of fire." Apparently what burst from the volcano was highly heated gas carrying with it immense quantities of white-hot volcanic ash. The vessel eventually reached the harbour of Castries, St. Lucia, and a survivor gave a correspondent of the *Times* the following account of his terrible experience:—

> No human being could stand against that terrific deluge of molten ashes. Even those who reached the cabin or hold did not escape, almost every nook and cranny of the ship being filled with the blazing dust. Captain Freeman sought shelter in the chart-room, but, the portholes being open, the fire streamed in and burnt him badly on face and hands.
>
> The heat was awful, for the mass of ashes which poured into the ship all aglow still retained its heat, and it was only with great difficulty and caution that it was possible to move about at all.

When the ship reached Castries, every part was found to be covered thickly with volcanic ash. More than 120 tons of ash were taken from the ship, and as this was precipitated in a white-hot condition it is remarkable that anyone passed through the burning storm alive.

The eruption of the Soufrière of St. Vincent was accompanied by the same kind of "hot blast" as that of Mont Pelée. Many victims of the St. Pierre disaster bore no outward sign of injury or scorching, but after autopsy they were found to have been burnt internally. A *Daily Mail* correspondent at St. Vincent records, from the words of a survivor, how most people died:—

> A dark cloud came from the Soufrière about 4 p.m., and a fine leaden powder penetrated doors and windows and filled the air. People breathed it in, and it was so hot it burnt the flesh. The people in the house began to cry out, and struggled, shouting for water, and placing their hands on their stomachs. They gasped, fainted, and died. All was over in three minutes. It is said that this hot blast killed most people, and wherever the powder touched people it burnt their flesh.

Prof. A. E. Verrill states in *Science* the opinion that the ejection of explosive gases was one of the causes of the sudden destruction of life in the Martinique eruption His view is as follows:—

> The heat was sufficient to cause the dissociation of hydrogen and oxygen from the water on coming suddenly into contact with highly heated lava, and in case of sea-water the chlorine would also be dissociated from the sodium. These gases suddenly ejected with great violence and exploding in the air, above the crater, would produce precisely the effects witnessed on an unusually large scale at Martinique. The people were mostly killed by the sudden explosion of a vast volume of hydrogen and oxygen, which will account for the sudden burning of flesh and clothes, as well as of the buildings and vessels. The chlorine, at the same time, combining with some of the hydrogen, would produce hydrochloric acid, a poisonous and suffocating gas, which would quickly kill most of those not instantly destroyed by the explosion.

As to the changes which have occurred at St. Vincent, it is reported that a party of American investigators who ascended the Soufrière found that the lake had disappeared, leaving a cavity 2000 feet deep. Vapour was still issuing from the new crater.

The Imperial Commissioner of Agriculture for the West Indies has informed Kew that the botanic station and agricultural school in St. Vincent are untouched beyond a fall of volcanic dust.

It is reported in the *Barbados Advocate* that the volcanic ash is adding to the difficulties of sugar-making. The dust is everywhere. It has worn some mill-rollers so smooth that they can hardly draw in the canes. In places the machinery is much injured, and everywhere the dust gets into the juice and has to be strained out, flannel bags having to be used to strain the liquor. On the evening of May 19 a fine dust of a light grey colour was observed to be falling on the Oxford plantation, and it was conjectured that it came from Mont Pelée, in Martinique.

The Royal Mail steamer *La Plata* had a fall of dust on board when between St. Vincent and St. Lucia, while the barque *Jupiter* had a heavy fall far to the eastward of Barbados. From the great mass which fell in the sea around the latter ship, actually colouring the water, it was known that some extraordinary phenomenon must have occurred. There was also such a darkness that lamps were alight at an unusually early hour.

Magnetic Disturbance.

Dr. L. A. Bauer reports in *Science* that a magnetic disturbance was recorded at two magnetic observatories of the U.S. Coast and Geodetic Survey on May 8, at 7.45 St. Pierre local mean time, that is, at the time of the great eruption. The disturbance was distinctively a *magnetic* and not a seismic one, and hence was not recorded on seismographs. The magnetograms obtained at Cheltenham, seventeen miles from Washington, exhibit magnetic disturbances amounting at times to 0·00050 to 0·00060 C.G.S. units (about 1/350 of the value of the horizontal intensity) and from 10′ to 15′ in declination, beginning at the time stated and continuing until midnight of May 9.

"Until further information has been received from other observatories," says Dr. Bauer, "it cannot be determined definitely whether this magnetic disturbance was due to some cosmic cause or came from within the earth's crust and was associated with the Martinique eruption. The coincidence in time is, however, a remarkable fact."

Earthquake of April 19.

Some valuable notes on the earthquake in Guatemala on April 19 are given by Mr. Rockstroh in a letter published on another page (p. 150), with a map of the district seriously affected. Prof. Milne obtained a record of this earthquake at Shide, and it was reproduced in NATURE of May 29 (p. 109). Miss G. M. Johnson sends us a cutting from the *Yorkshire Post* of April 19 containing several letters upon an earthquake which was distinctly felt in parts of Yorkshire and Lincolnshire on April 14. At Beverley the time noted was 11.51 a.m., at Greetwell 11.45, and Hatfield 11.40. At Belton the disturbance shook a bedstead four inches from its place.

Volcanic Ash from Mont Pelée.

Prof. T. G. Bonney writes :—

I am indebted to Sir W. Crookes for a mounted specimen of the dust from Mont Pelée, which fell on the deck of the *Roddam*. The fragments are commonly about ·007″ in diameter, but range between ·005″ and ·01″, minerals and rocks being in about equal quantity, the former consisting of labradorite, augite (bottle-green) and a pleochroic (green to brown) hypersthene, the latter rather scoriaceous, a brownish-grey in colour. I have mentioned some minor details in a short communication to the Geological Society. This dust has a general resemblance to that from the Soufrière which fell in Barbados, and both represent hypersthene-andesites.

Analyses of Soufrière Dust.

For educational purposes all the agricultural colleges in this country, and a number of the principal schools—Westminster, Harrow, Eton, Rugby, &c.—have received from Mr. Harries, of the Meteorological Office, a sample of the Soufrière dust which descended on Barbados during the night of May 7–8. It had been collected by Dr. Morris, the Imperial Commissioner of Agriculture, as it fell, and a portion submitted to investigation at the Government Laboratory on the spot yielded the following results :—

Prof. d'Albuquerque's chemical analysis showed the substances soluble in strong hydrochloric acid to be :—

	Percentage.		Percentage.
Iron oxide ...	4·7	Silica ...	·1
Alumina ...	12·5	Sulphuric anhydride...	·1
Lime ...	5·9	Insoluble in hydrochloric acid :—	
Magnesia ...	·78	Silicates ...	75·2
Soda ...	1·2		
Potash ...	·08		

Also a trace of sulphides and a faint trace of sulphurous anhydride—a product of the combustion of sulphides and sulphur.

The mineralogical examination by Dr. Longfield Smith gave the following as the results of the sieve analysis :—

Diameter of particles.	Percentage.
1 to ·5 millimetre	0·01
·5 „ ·35 „	3·06
·35 „ ·20 „	7·21
·20 „ ·15 „	66·20
·15 „ ·10 „	0·89
·10 and less „	22·63

The particles from ·5 to ·35 mm. diameter were wholly composed of volcanic glass crowded with gas inclusions and containing small lath-shaped crystals of felspar. The gas inclusions in many instances were so numerous as to render the particles quite opaque. The particles of ·35 to ·2 mm. were of similar volcanic glass and partly of crystals of felspar. Those of ·2 to ·1 mm. were almost entirely composed of mineral crystals, consisting chiefly of lime and soda felspar and of a ferromagnesian mineral not yet definitely determined. They also contained a quantity of magnetite and a very few crystals of a dark blue doubly-refracting mineral not yet determined. The particles finer than ·1 mm. were chiefly composed of comminuted fragments of felspar.

A comparison of the dusts of 1812 and 1902 points to the recent eruption as being much the more violent, it being very rare to find so many mineral particles in volcanic dust scattered so far from the seat of eruption. The fact that particles of magnetite, a mineral of specific gravity 5·5 to 6·5, of more than 1 mm. diameter, should be found in the dust more than ninety miles from the seat of explosion is significant of the prodigious height to which the particles must have been ejected.

The subjoined diary of events is in continuation of those already given.

Diary of Events.

June 4, *Kingstown* (*St. Vincent*).—Vessels leaving Martinique have experienced upheavals of the sea between that island and St. Lucia, indicating submarine eruptions. Clouds of steam, accompanied by flashes of flames at night, have been continually rising from the Soufrière since May 16.

June 4, *Cornwall.*—A slight shock of earthquake was felt in the neighbourhood of Camborne about 10.20 p.m. It was accompanied by a low rumbling noise. In some houses ornaments were shaken from the shelves on which they stood.

June 4, *Valparaiso.*—According to a despatch from La Paz, a volcanic eruption has occurred in the Choicó (Chaco ?) territory, by which two villages were destroyed and seventy-five persons killed.

June 4, *Baku.*—The journal *Kaspi* reports an eruption of the mud volcano in the neighbourhood of the village of Kobi, district of Baku. The eruption, which lasted about five minutes, was accompanied by a detonation resembling the report of cannon, and the country around for some distance was enveloped in flames.

June 4, *Rome.*—A slight earthquake shock was felt last evening at Velletri, twenty miles south-east of Rome. No damage was done.

June 6, *Melbourne.*—A slight earthquake shock was experienced in South Australia to-day.

June 6, *Seattle.*—The steamer *Berthaw*, which has arrived from Alaska, brings advices to the effect that the volcanic mountains Redoubt, Llanna and Augustine at Cook's inlet have been smoking and giving off steam for a month past. On May 26 Mount Redoubt threw up a quantity of ashes.

June 6. *Fort de France.*—Another eruption of Mont Pelée took place to-day. A gigantic cloud extended to the south, covering Fort de France with darkness, but no ashes fell. The sea here receded for several feet, and did not return for some time.

June 6, *Kingstown* (*St. Vincent*).—Simultaneous with an eruption of Mont Pelée, the Soufrière in St. Vincent belched out a heavy cloud of smoke, and at 2 p.m. Kingstown was wrapped in pitch darkness.

June 7, *Fort de France.*—A terrible eruption took place. Fort de France was in darkness from 10 a.m. until 2 p.m. The plains of the Morne Rouge were covered with hot mud.

June 7, *Hawaii.*—The volcano Mauna Loa has become active.

THE NEW BOTANICAL LABORATORIES AT LIVERPOOL.

As already announced, the new botanical laboratories, presented to University College, Liverpool, by Mr. W. P. Hartley, of Aintree, were formally opened on Saturday, May 10, by Sir William Thiselton-Dyer, K.C.M.G., F.R.S., Director of the Royal Botanic Gardens, Kew. The laboratories, of which a sketch elevation has already appeared in NATURE (vol. lxi. p. 454, March 5, 1900), vie, both in size and equipment, with those of the University of Glasgow, opened last year by Sir Joseph Hooker.

The building, which is plain and unpretentious externally, covers an area of 3000 square feet, and consists of three main floors, accommodating the museum, lecture theatre and elementary laboratory behind, whilst by the interpolation of two mezzanines facing the main thoroughfare, space is found for private rooms, research laboratories, herbarium, class room and workshops. All the rooms open off a central staircase, lit from a lantern in the roof, thereby avoiding waste of space in the provision of corridors. A basement contains the store-rooms, lavatories and heating chamber; the ground floor is occupied by the museum, museum preparation room and workshop. The first mezzanine carries the herbarium and class room, with an entrance to the gallery of the museum. On the first floor is placed the theatre, seated for two hundred students, the professor's private room with a private laboratory adjacent, and the departmental library. On the second mezzanine are placed the research laboratories and dark room, whilst the second floor is occupied by the elementary laboratory, with accommodation for sixty-five students, the advanced laboratory, arranged to seat twenty students, and the assistant lecturer's private room.

Fig. 1.—Hartley Botanical Laboratories, Liverpool.

The laboratories, museum and lecture rooms are fitted with pitch-pine and teak fixtures, and the building is lit throughout by electric light. All the laboratories, both public and private, are equipped with gas and water fittings, and baywood wall cases are provided for storage of apparatus and materials. The total cost of the building has been somewhat more than 13,000*l*., including the cost of the freehold and 750*l*. expended on museum glass and essential physiological apparatus.

The opening ceremony took place in the arts theatre of the College, where a large audience was presided over by Mr. E. K. Muspratt, vice-president of the College, in the unavoidable absence of the president, Lord Derby. Amongst other botanists present were Sir William Thiselton-Dyer, Profs. Marshall Ward, Bretland Farmer, Weiss, Potter, Bottomley and Smith, and Mr. Wager. Sir Michael Foster, who expected to be present, was detained at the last moment by parliamentary business. Among the general guests were Sir John Brunner, M.P., Sir John Willox, M.P., Prof. Miller Thompson, Prof. Lord, &c. The principal was accompanied by a large number of the College staff.

Mr. W. P. Hartley, in formally presenting the laboratories to the College, said that the citizens of Liverpool desired their city to be foremost, not only in commerce, but in knowledge, in the discovery of truth and the encouragement of science in its pure as well as in its applied branches. His object in providing the laboratories to the College was to help in the realisation of that ideal.

After the formal acceptance of the munificent gift by the chairman and the principal of the College (Prof. Dale), a vote of thanks to the donor was carried by acclamation and responded to in suitable terms by Mr. Hartley.

Sir William Thiselton-Dyer then delivered an address on the value of the study of botany as a means of cultivating the powers of observation and deduction from observed facts. He said his feeling in coming to the north from the metropolis was one of envy. He found a great commercial city full of busy life, possessing buildings and equipment for the pursuit of knowledge marked by a sumptuousness and magnificence the like of which was not possessed by them in London, and which they had little hope of obtaining. That grand municipal spirit existing among Liverpool citizens showed a height of local patriotism to which they had not attained in the metropolis. It was a lasting glory to her that Liverpool had undertaken so great a work, and he could not doubt that a blessing would come upon her citizens in the stimulus to that higher life the seeds of which they had planted.

The new laboratories, as the generous donor had said, were not intended to teach merely that which would lead to direct profit, they were intended also, and primarily, as a centre for the prosecution of research and study not necessarily utilitarian in its aim. The study of botany was calculated to foster to the highest degree the faculties of observation and deduction. Bluntness of observation was a national calamity, for the inability to see a thing at the moment it presented itself might mean the loss of a unique opportunity. Not in botany alone, but in all

studies and occupations, the seeing eye was of infinite—even fundamental—service.

After a brief *résumé* of the history of botany in England and an appreciation of the services rendered to the science by men like Grew, John Ray, Robert Brown and others, Sir William expressed the hope and belief that England would again attain and retain the premier place in botanical study and research, and that the botanists of Liverpool would so use their splendid opportunities as to maintain the reputation of their country. He went on to speak of the great industries which had their origin in botanical discoveries, of the value of the science to medicine, and pointed out a fact too often overlooked that plants were intimately connected with every phase and stage of human life until, in the final act of the drama, they facilitated our decay.

After a vote of thanks to Sir William Thiselton-Dyer for his address, proposed by Sir John Brunner, M.P., and seconded by Prof. Harvey Gibson, and the presentation of memorial keys to Mr. Hartley and Sir William Thiselton-Dyer, the guests adjourned to the Hartley Laboratories, which were thrown open for inspection.

FIG. 2.—Elementary Laboratory. Hartley Laboratories, Liverpool.

THE HUGH MILLER CENTENARY.

THE proposal to celebrate the centenary of the birth of Hugh Miller during the present year has met with general approval, and the erection of an institute bearing his name in Cromarty has been admitted to be the best means of appropriately celebrating his memory.

It is intended that the Hugh Miller Institute shall take the form of a museum, where any relics pertaining to Miller can be kept; and a free library and reading room.

The centenary committee have had the promise of support from Hugh Miller's admirers in America and the colonies, as well as at home, and Mr. Carnegie, the generous supporter of such institutions as the proposed institute, has made the handsome offer to give 100*l.* for every 100*l.* raised by the committee.

It is desirable that the memorial should be as widely representative as possible, and the committee therefore appeal to all who appreciate the work accomplished by Hugh Miller in science and literature for contributions, in order that the scheme may be sufficiently advanced by the aniversary of his birth in October.

Contributions should be sent to the Treasurer, Commercial Bank, Cromarty.

The movement has the support of the following:—

Lord Balfour of Burleigh, Secretary for Scotland; Sir Archibald Geikie, F.R.S., LL.D.; Prof. Masson, LL.D.; Sir John Leng, M.P.; Sir Walter Foster, M.P.; C. J. Guthrie, K.C., Sheriff of Ross and Cromarty; W. C. Smith, LL.B.; Prof. Duns, Edinburgh; A. Taylor Innes, Esq., Edinburgh; Prof. Clarke, State College, New York; W. Robertson Nicol, LL.D.; A. Bignold, Esq., M.P.; Principal Rainy, D.D.; Alexander Whyte, D.D.; Colonel Ross, C.B., of Cromarty; Mr. James Barron, *Inverness Courier*; W. J. Watson, B.A., Secretary Inverness Field Club.

J. BAIN, Hon. Sec.,
Hugh Miller Centenary Committee.

Cromarty, May, 1902.

LAZARUS FUCHS.

THE name of Lazarus Fuchs will always be associated with the theory of linear differential equations, to which he gave an extraordinary impulse by his famous memoir published in the sixty-sixth volume of Crelle's *Journal*. In this paper the methods of modern function-theory are brought to bear upon the long-familiar process of solving a differential equation by series. The coefficients of the equation being supposed to be uniform analytical functions with isolated singularities, it is shown how to obtain, in the neighbourhood of an ordinary point, a complete set of independent integrals; the analytical form of these solutions is determined, and shown to depend upon a certain fundamental or indicial equation. It is proved, also, that the singularities of the integrals may be deduced from the coefficients without integration, and the notion of regular integrals is developed. The distinction is made between the integrals which involve logarithms and those which do not, and attention is drawn to those equations the integrals of which have no essential singularity. Thus in a single memoir of moderate length all the essential features of an extensive theory are presented in a clear and comprehensive outline.

In the rapid development which followed the publication of this memoir, the author naturally took a prominent part. Among his important contributions may be mentioned his researches on linear equations with algebraic integrals, on constructing linear equations the integrals of which have assigned singularities, and on equations the integrals of which are connected by algebraic relations. An instructive illustration of the general theory is given by his memoir on the equation satisfied by the elliptic integrals K, K′.

When the independent variable describes a closed curve, a set of integrals undergo a linear substitution, and all the substitutions arising from different paths form a group associated with the equation. M. Poincaré assigned the name of Fuchsian functions to functions invariant for a group of linear transformations of the variable in recognition of Fuchs's results concerning equations of the second order.

Fuchs's mathematical papers are very pleasant to read and free from that tendency to heaviness which is apt to belong to memoirs on differential equations. He had the faculty of bringing out clearly the really important points without over-elaborate detail, and he did not disdain to show the power of his methods by applying them to specific and definite problems. In these respects he may be compared with Halphen. While admitting that his way was prepared by the work of Cauchy, Briot and Bouquet, and Riemann, we may fairly claim for him that he has been the effective pioneer in a vast and fascinating region.

It is interesting to remember that Henry Smith, in a presidential address to the London Mathematical Society

in 1876, directed attention to the importance of Fuchs's then recent publications. How true was his forecast, that "they must form the basis of all future inquiries on this part of the subject," the history of the years that followed has fully shown.

Fuchs was born at Moschin (Posen), May 5, 1833; he became extraordinary professor at Berlin in 1866, ordinary professor at Greifswald in 1869, at Göttingen in 1874, at Heidelberg in 1875, and finally at Berlin in 1884. G. B. M.

CARLO RIVA.

ITALIAN geology has sustained a heavy loss in the death of the young and accomplished Docent in petrography and Assistant in the mineralogical laboratory of the University of Pavia, Dr. Carlo Riva, who was killed by an avalanche on the 3rd inst. while ascending Monte Grigna. Besides contributing descriptions of various Italian minerals, he specially interested himself in the study of the volcanic rocks of Italy, and in conjunction with his friend G. de Lorenzo he had been for some time engaged in a detailed investigation of the volcanic cones and rocks of the "Campi Phlegræi." The first fruits of this conjoint labour appeared a year or two ago in a monograph on the remarkable but seldom visited cone of the island of Vivara, which was noticed in NATURE last year. Never before had such a combination of geological and petrographical skill been devoted to any of the old volcanoes of that classic district, so that geologists who had seen the memoir looked forward with much interest to the application of the same talents to the other cones. It is understood that the account of Astroni was far advanced towards completion. But all this bright promise of a career that would have advanced the cause of science and shed lustre on the scientific work of Italy has been abruptly quenched. Those who knew Carlo Riva personally will keenly feel the untimely extinction of a nature so gentle and kindly, so enthusiastic and unwearying in pursuit of science, so full of power and yet so modest and retiring. He has died a martyr to the energy with which he followed his favourite studies, and carries with him to the grave the respect and affection of a wide circle of friends.

A. G.

NOTES.

THE Prince and Princess of Wales were present at the Royal Institution on Friday last when Sir Benjamin Baker delivered a lecture on "The Nile Dams and Reservoir." Before the lecture several striking experiments were shown to their Royal Highnesses by Lord Rayleigh, Sir William Crookes, Prof. Dewar and Prof. Macfadyen.

THE Rome correspondent of the *Daily Mail* announces that the Accademia dei Lincei has decided to give Mr. Marconi a prize of 400*l.* as a reward for his work with wireless telegraphy. From the same source we learn that Mr. Pierpont Morgan has presented a set of cut precious stones, valued at 2000*l.*, to the museum of the Jardin des Plantes, at Paris.

SEVERAL correspondents have sent to the daily papers accounts of the fall of a yellow powder on June 1 and 2 during a thunderstorm. At Great Yeldham, in Essex, and at Langport, Somerset, this yellow sediment was found after the storm had subsided, and was thought to be sulphur. Mr. C. Turner has, however, pointed out in the *Times* that the substance supposed to be sulphur is in reality the pollen from pine trees. This is often produced in large quantities and has many times been mistaken in country places for "showers of sulphur."

MR. F. FINN sends us from Calcutta an account of colour variation in a family of pigeons which have sprung from a pair of homing pigeons imported from England last year. "Of the original pair," he says, "the cock is a blue chequer and hen a silver chequer. None, however, of their descendants have been silver, but all blue chequers, with the exception of one, a blue almost exactly resembling the wild *Columba livia*, but with no white on the back. As against this one case of reversion, there have been two of progressive variation; for two birds, grandchildren of the original pair, though of different broods, show white in the tail, though their parents and grandparents had none." A naturalist to whom the observations have been shown remarks:—"The production of white feathers in the tail I should hardly regard as a case of progressive variation. It is more probably a reversion to some previous ancestor. Homing pigeons are not bred for colour, and it is almost certain that some of the ancestors of the pair sent would have had white feathers in the tail."

AT the forthcoming meeting of the American Association at Pittsburg, several of the sections and affiliated societies will meet in the Carnegie Institute, where the offices and reception room of the Association will also be situated. The accompanying view of the Institute is reproduced from the preliminary programme of the meeting. The local committee is a large one and contains many leading men and women connected with Pittsburg; Mr.

Carnegie Institute, Pittsburg.

George Westinghouse, jun., is the president. It is noteworthy as evidence of sympathy with scientific efforts that the following resolutions were adopted unanimously on March 24 by the Federation of Churches at Pittsburg, Allegheny and vicinity:—"Inasmuch as all truth is one and is divine and inasmuch as all organisations for its conservation and propagation are kindred, the Federation of Churches of Pittsburg, Allegheny and vicinity records its pleasure in the fact that the American Association for the Advancement of Science is to hold its anniverary in Pittsburg this year. In behalf of the churches we desire a large and representative meeting here of the seers and prophets of science. In behalf of those interested in the advancement of education and knowledge we extend to them a hearty welcome."

THE seventh annual congress of the South-Eastern Union of Scientific Societies, held at Canterbury on June 5-7, was as successful as any of the preceding ones. Thirty-seven societies are now affiliated to the Union, a slight increase on last year; the accounts showed a small balance, and the attendance was good. An invitation to meet at Dover next year was accepted, and Sir Henry Howorth, F.R.S., was elected president for that meeting. Papers were read on "The Marine Aquarium," by Mr. Sibert Saunders, and on "Mycorhiza," by Miss A. Lorrain Smith; Prof. Poulton gave a lecture on "Recent Researches on

Mimicry in Insects," illustrated by lantern-slides in natural colours; a discussion on the measures to be adopted for the preservation of our indigenous flora was initiated by Prof. Boulger and Mr. E. A. Martin; and papers on "Well-sections," by Mr. Whitaker, and on "Eolithic Flint Implements," by Mr. E. R. Harrison, were taken as read, but will appear in *The South-Eastern Naturalist* for 1902. The event of the meeting, however, was the address by the president, Dr. Jonathan Hutchinson, F.R.S., on leprosy, with special reference to its antiquarian aspects, with reasoned argument against the theory of contagion. The congress was held, by permission of the governors, in the Simon Langton Schools, where an excellent local museum had been got together, including marine aquaria exhibited by Mr. Saunders, Mr. Harrison's eoliths, and many fresh specimens of the British orchids, so well represented in the district. The members visited the Cathedral, and were entertained at the deanery by the Dean and Mrs. Farrar, and were also received, on the Friday evening, by the Mayor and Mayoress. The congress terminated on the Saturday afternoon in a visit to the South-Eastern Agricultural College, Wye, at the invitation of the principal, Prof. A. D. Hall, where the members were shown over the farms and laboratories by the staff of the college.

A CURIOUS effect produced by lightning is described to us by Dr. Enfield, writing from Jefferson, Iowa, U.S. A house which he visited was struck by lightning so that much damage was done. After the occurrence, a pile of dinner plates, twelve in number, was found to have every other plate broken. It would seem as if the plates constituted a condenser under the intensely electrified condition of the atmosphere. The particulars are, however, so meagre that it is difficult to decide whether the phenomenon was electrical or merely mechanical.

A REPORT upon a Bill for the adoption of the metric system of weights and measures in the United States was recently submitted to the U.S. House of Representatives by the Committee on Coinage, Weights and Measures. The report recommends strongly that the Bill be passed and the use of the system made compulsory because of its international character, educational benefits and commercial advantages. The scientific world to-day enjoys the advantages of a universal system of weights and measures, and this fact has doubtless facilitated the development and spread of natural knowledge. With regard to the introduction of the system into a country, the experience of other nations has shown that the confusion and inconvenience caused by a change in the measures used in daily life are largely over-estimated. Finally, the committee remarks:—"It should be kept in mind that the metric system is just as capable of a binary subdivision as any other, although the advantages of such a division are only apparent in the most ordinary business transactions and for the first few subdivisions. After the adoption of the metric system, the use of the half and quarter metre and half and quarter kilogramme would be as common as our half and quarter dollar—smaller quantities would be expressed in decimals precisely the same as in the case of our money. In 1866, Congress legalised the metric system. From that time on it has been growing in favour and in practical use. It is here to stay, not only in scientific work, but in commerce and manufacturing. It is now used by about two-thirds of the people of the world. . . . . Your committee believe the time has come for the gradual retirement of our confusing, illogical, irrational system and the substitution of something better. The first step in this direction should be the introduction of the metric weights and measures into the departments of the Government. The use of these weights and measures will simplify their work. It will familiarise the people with them and encourage their application to the common affairs of life. Your committee have no doubt that the benefits to be derived will far more than compensate for such inconvenience and expense as may be involved in the change."

EXPERIMENTS with a system of wireless telephony are being carried out (according to the *Scientific American*) in America by Mr. Stubblefield. The results so far have been of a promising nature, conversation having been successfully transmitted over several hundred yards on land and several hundred feet on water. The system used is an earth-conduction one, and is, therefore, similar in principle to, though doubtless differing in detail from, many other wireless telephony systems which are being tried in various countries. We have had occasion to comment on these in NATURE from time to time during the past year. It cannot be said that the results which have as yet been obtained by any of the experimenters are of sufficiently striking value to justify the prediction of a great future before this method of communication. But it is evident that many inventors are attacking the problem, and it is likely, therefore, that something of practical utility may be developed by their efforts. It is easy to conceive of many circumstances in which an earth-conduction telephonic system, even of limited range, would be very valuable.

A PAPER on the accuracy of an improved form of silver voltameter, by Messrs. T. W. Richards and G. W. Heimrod, is published in the *Proceedings* of the American Academy of Arts and Sciences for April. The silver anode is suspended in a porous pot, which is itself hung inside the platinum crucible serving as kathode. The level of the nitrate solution inside the porous pot is kept slightly lower than that outside, and thus outward filtration of the anode liquid is prevented. The authors not only examined the accuracy of the voltameter, but made a valuable investigation of the effects of the various impurities likely to result from irregularities in the electrolysis or anode. As a result of this, and from the data furnished by the experiments with the porous pot voltameter, corrections are deduced for the determinations of the electrochemical equivalent of silver made by Lord Rayleigh and Mrs. Sidgwick, F. and W. Kohlrausch, Kahle, and Patterson and Guthe respectively. The corrected figures give a mean result of 0·0011175, none of the four individual values differing from this by more than 0·02 per cent. Hence the number of coulombs associated with one gram-equivalent of any electrolyte is 96,580.

A PAPER on the sensitiveness of the coherer, by E. R. Wolcott, appears in No. 51 of the *Bulletin* of the University of Wisconsin. The experiments were carried out with coherers of two pieces of metal in light contact, as it was found that these gave more consistent results than "filings" coherers. Different metals were tried, and also the effect of coating different metals with a film of the same substance, such as collodion. The author concludes that both the metal and the coating affect the sensitiveness. Aluminium was found to be the most regular in response, but nickel showed the lowest critical potential, that is to say, responded to the least energy; this probably accounts for its value in long-distance wireless telegraphy. The author examines his results with reference to the theories of the coherer's action put forward by Branly, Lodge, Bose, and Guthe and Trowbridge. Guthe and Trowbridge's theory explains more of the phenomena than do any of the others, though all the observed facts are admissible on Lodge's theory. Some of the facts, it is said, are in disagreement with the theories advanced by Branly and Bose.

DR. C. DIENER contributes to the *Jahrbuch der k.-k. geol. Reichsanstalt* (Band li. Heft 2) an appreciative article dealing with the scientific work of Albrecht von Krafft, whose untimely

death in September last year brought to an end a career of great promise. Dr. von Krafft had already earned his reputation as an able geologist while occupied on the Geological Survey of Austria, previous to joining the staff of the Geological Survey of India in 1899. In that year, and subsequently, he accomplished brilliant work in the Himalayas, and showed himself to be exceptionally well qualified for the difficult tasks allotted to him. His early death at the age of thirty has caused the profoundest regret in geological circles.

THE Royal Meteorological Institute of the Netherlands has issued its fifty-first year-book, containing observations for 1899. This is the first volume of a new series, in which the results are presented in the form adopted by the International Meteorological Committee, and is a great improvement upon the form in which the observations have hitherto been published.

MR. MAXWELL HALL has published a paper (No. 275) on the temperatures of Kingston, Jamaica, for the years 1881–98. The annual mean is 78°·8, highest maximum 96°·7, in August 1891, lowest minimum 56°·7, in December 1887. The lowest mean maxima occurred in 1884 and 1893, near the times of the sun-spot maxima, and the highest in 1889, at the time of the sun-spot minimum, and these effects are reproduced in the mean temperature column. A table is also given showing the rainfall in Jamaica from about ninety stations between 1866 and 1900; the greatest fall was 90·6 inches, in 1886, and the least 45·2 inches, in 1872.

MR. R. SWORDY sends us a few particulars of a somewhat remarkable shower of hailstones which fell in Cheltenham and the surrounding district on June 7, shortly before noon. At first the hailstones were more or less round and like small crystallised raspberries; but during the latter and main part of the shower they were in the form of wedges or small cones, somewhat varied in shape. Many of these hailstones were about three-quarters of an inch in height and measured about half an inch across. Mr. Swordy suggests that these were only conic sectional parts of what had been much larger hailstones. To test this view he put some selected ice cones in a circle and added two more layers upon the first circle and a key wedge or cone at the top. By this arrangement he obtained half an ice-ball, consisting of fifteen sections. The hailstones when first formed may therefore have been about the size of "ping-pong" balls, and about an inch and a half or two inches in diameter. Mr. Swordy adds:—"The grain of the ice in these sections (which, I presume, had formed the balls originally) radiated from the centre towards the outside, and were hardest on what I suppose had been the outside; so that it is probable that the freezing, which must have commenced from the outside of each water globule and progressed towards the centre, thus bringing pressure to bear on the centre of each ball, may have caused them to explode and form the cones mentioned."

IN a note on "mathematical meteorology," Prof. Luigi de Marchi contributes to the Lombardy *Rendiconti* an investigation of the equations of motion of air-currents due to variations of temperature, with especial reference to the effect of solar eclipses. The action of an eclipse, it is pointed out, is to produce what Mr. Helm Clayton has called a cyclone with a cold centre.

WE have received from Messrs. A. E. Staley and Co. a copy of the fourth edition of "Manipulation of the Microscope," by the well-known optician, Mr. Edward Bausch. It is a small illustrated handbook specially designed to meet the wants of beginners, and the sections dealing with the use and care of the microscope have been reprinted for distribution in class-rooms and laboratories.

NO. 182 of the *Bulletin* of the French Physical Society contains a note on a new "electric valve" for transforming reciprocating currents into direct currents, due to M. Nodon. This "valve" is based on the property, discovered by Buff in 1857, that an aluminium electrode plunged in an electrolyte offers a great resistance to the passage of a current in which it is the anode. The efficiency of M. Nodon's apparatus, as measured by a wattmeter, reaches 75 to 80 per cent.

AN oxy-acetylene blowpipe is described by M. Fouché in the *Bulletin* of the French Physical Society, No. 182. The flame is formed by the combustion of a mixture of one part of acetylene to 1·8 of oxygen, and in order that the explosion may not travel back into the blowpipe a jet velocity is required due to the pressure of a water column 4 metres in height. The flame melts most metals readily; it will solder iron and steel, and even silica and lime are melted by it. With a reduction of the proportion of oxygen the flame becomes luminous, and on falling on lime the free carbon goes to form carbide of lime.

IN the *Rendiconto* of the Naples Academy, viii. 2. Signor E. Cesàro deals with certain limitations of constants in the analytical theory of heat. His investigation refers to the property that in order to satisfy the partial differential equation $\nabla^2 u + ku$ throughout a given region S, subject to the boundary condition $du/dn + hu = 0$ at the surface of S, the constant k must for a given value of h belong to a discrete series of positive quantities, which all increase with h. The author also discusses the question of the expansion of the temperature due to an initial distribution in a series of functions of the form considered.

PROF. LE NEVE FOSTER has given a useful practical address on the study of mineral veins (*Trans.* Royal Geol. Soc. Cornwall, vol. xii. part vii.). Mr. J. B. Hill, in dealing with the relation of the plutonic and other intrusive rocks in west Cornwall to the mineral ores, expresses the opinion that the intrusion of the greenstones was separated by no great interval from the irruption of the granites, and that the copper and tin lodes originated in pre-Triassic times and followed closely on the cooling of the intrusive rocks.

A *Bulletin* issued by the U.S. Department of Agriculture concerning Kentucky bluegrass seed affords a striking instance of the amount of trouble which Americans will take to improve a product of comparatively trifling value. The cultivation of bluegrass is confined to a small area in the States of Kentucky, Missouri and Iowa. The harvesting is performed entirely or partially by hand, as automatic strippers do not seem to find favour.

THE latest number of the *Journal* of the Royal Horticultural Society completes the twenty-sixth volume. Two articles of an economic nature suggest to fruit-growers the possibility of making a profit out of surplus fruit. Mr. Austin claims to have devised a practical and efficient method of putting up fruit in bottles, while Mr. Udale brings forward the results obtained by drying fruits and vegetables in special evaporators. There is no apparent reason why the British farmer should not take up these industries and possibly oust imported articles. Captain Hurst having made a study of the characters of certain orchid hybrids, finds that they confirm the laws evolved by Mendel as the outcome of his experiments in hybridisation.

THE Report of the Zoological Society of Philadelphia for 1901 shows that the institution is in a flourishing condition. It is satisfactory to learn that the educational value of the menagerie is fully realised by the public schools of the city, which are in the habit of sending parties of scholars accompanied by teachers.

WE have received a copy of the second edition of the excellent little manual of the fauna and flora of Haileybury, issued by the Haileybury Natural Science Society under the supervision of Mr. F. W. Headley. The compilation and publication of similar local lists may be recommended to all school societies of a like nature.

IN the *Verhandlungen* of the Natural History Society of Prussian Rheinland, &c., for 1901, Dr. O. Follmann describes and figures an interesting new type of crinoid from the "Coblenzschichten" under the name of *Hystricrinus schwerdii*. To the same journal Herr Leverkus-Leverkusen, of Bonn, contributes an account of the present and past distribution of the elk.

The Country for June contains several interesting and well-illustrated articles on subjects connected with natural history and domesticated animals. Mr. W. F. Kirby, for instance, writes on common garden insects, while Mr. Harrison Weir discourses on the old English game-fowl, and Mr. Edwin Brough, of Scarborough, the well-known breeder of bloodhounds, describes some of the characteristic traits of his favourites.

AN important account of the ascidians of the Bermudas, by Dr. W. G. van Name, appears in the January and February issues of the *Transactions* of the Connecticut Academy (vol. xi.). The seas around these islands are remarkably rich in ascidians, and since but little has previously been done in the way of collecting, the writer has been able to describe quite a number of new types, both generic and specific. The memoir is illustrated by several plates.

ACCORDING to *Nature Notes* for June, the Society for the Protection of Birds has just issued the regulations and conditions for the first annual competitions open to elementary schools in the East Riding of Yorkshire and in Berkshire for challenge-shields and prizes in connection with "bird and tree day." The day is to be in November—probably the 8th—and essays are to be sent in during September. Any bird killed, or any eggs or nests taken for the purposes of the competition, will disqualify not only the actual offender, but all his fellow-scholars.

AT an egg-sale recently held at Mr. Stevens's auction rooms, Covent Garden, a moa's egg from New Zealand, reputed to be the finest in existence, was offered. Since, however, it did not reach the reserve price of 200*l*. it was withdrawn. Another example was sold some years ago for 250*l*. Thirty-eight guineas was the sum realised by the largest known egg of the extinct "roc" (*Æpyornis maximus*) of Madagascar; while two eggs of the pectoral sandpiper—the first of their kind ever offered in England—fetched 8*l*. 18*s*. 6*d*.

THE insect-enemies of the pine in the Black Hills Forest Reserve form the subject of *Bulletin* No. 12 (second series) of the Entomological Division of the U.S. Department of Agriculture. According to the author, Dr. A. D. Hopkins, the forests of rock-pine in the district in question have suffered very severely of late years from insect-ravages, the dying or dead trees covering large areas. The primary cause of the mischief is a small bark-burrowing beetle of a species hitherto undescribed, for which the name *Dendroctonus ponderosa* is suggested. After the first attack by this species, several other insects aid in the work of destruction. Various remedies are suggested by the author.

THE *Eastern Morning News* of June 3 contains an account of the reopening, by the Mayor, of the museum at Hull, which was some time ago taken over by the Corporation from the Literary and Philosophical Society. Since the transference, the contents of the museum have been thoroughly overhauled and rearranged by the curator, Mr. T. Sheppard, who has introduced order and system where chaos formerly held sway. The value of the exhibits is estimated at considerably more than 5000*l*.; many specimens of interest cannot, however, be shown for lack of proper cases. At the opening ceremony it was announced that the fine collection of British birds' eggs formed by the late Mr. J. Swailes had been presented to the museum by his brother, Mr. G. Swailes. In the rearrangement of the collections the educational value of the museum has been specially borne in mind.

A LECTURE on the natural history of the Chatham Islands, delivered by Dr. A. Dendy on March 4, is reported at length in No. 12 of vol. xlvi. of the *Manchester Memoirs*. Chatham Island and the adjacent Pitt Island appear to have once formed a portion of New Zealand, and are of especial interest as being the home of the Moriori, a race nearly exterminated by their cousins the Maori between 1835 and 1840. After giving a brief sketch of the flora of the islands, the author turns to the fauna, which, as might be expected, is nearly akin to that of New Zealand. Especially noticeable is the number of flightless birds, most of which are in danger of extermination owing to the introduction of predatory mammals.

TOTEMISM is a blessed word, and there is a real danger at the present time that any animal cult may be relegated in an off-hand manner to totemism. The very careful study of the relations between men and animals in Sarawak by Drs. Charles Hose and McDougall in vol. xxxi. of the *Journal* of the Anthropological Institute (p. 173) is, therefore, especially welcome, as it is the result of many years of observation on the part of one of the authors among most of the important peoples of Sarawak.

NO less than 150 periodicals and publications of scientific and technical societies are now regularly abstracted in *Science Abstracts*, so that the magazine takes a comprehensive view of progress in physical sciences and their applications. Among recent additions to publications abstracted are several Russian, Danish, Dutch, Norwegian and Swedish journals which are only accessible to a limited circle of readers, though many important papers are published in them. The abstracts will enable workers in physics and physical chemistry to keep in touch with practically every advance in their subjects.

SCIENCE is represented in the *Fortnightly Review* for June by two popular articles—one by Mr. Marconi, on "The Practicability of Wireless Telegraphy," and the other by Mr. Carl Snyder, on "Dr. Loeb's Researches and Discoveries." Beginning with the message sent in June, 1898, by Lord Kelvin "commercially paid at Alum Bay for transmission through ether" to Sir George Stokes at Cambridge, an account is given by Mr. Marconi of the messages since sent, without wires, from the Royal yacht, in connection with the international yacht race, and the United States Navy trials. Mr. Synder describes and interprets the work accomplished by Dr. Loeb at Chicago University in the domain of chemical physiology, and that on which Dr. Matthews is engaged in the same institution in connection with nerve functions.

VOL. xl. of the *Zeitschrift für physikalische Chemie* contains a publication, by C. Benedicks, on the electrical conductivity of steel and pure iron, the investigation of which has given some very interesting results. It is shown that equivalent quantities of different elements, when dissolved in iron, increase the electrical resistance by the same amount. This is proved experimentally in the case of carbon, silicon, manganese and phosphorus, the increase of the resistance for one dissolved atom per one hundred atoms of the solution being 5·9 micro-ohms per cubic centimetre. The presence of carbide in the iron has, on the other hand, very little influence on the resistance. From the

electrical data certain conclusions have been drawn which are no doubt of considerable importance for the chemistry of steel and iron.

MESSRS. LONGMANS, GREEN AND CO. have just published new editions of two well-known works of science—Ganot's "Physics" and Schafer's "Essentials of Histology." Dr. Atkinson's translation of Ganot's "Éléments de Physique" has long been accepted as a standard description of the groundwork of physical science, and the sixteenth edition, edited by Prof. A. W. Reinold, F.R.S., will increase the high reputation the book has gained. Though physical science, even in its most elementary stages, needs to be studied practically to be of any value, the results obtained in the laboratory can only be fully understood by considering them in relation to the investigations of makers of scientific history. The best instruction in physics is that which combines a course of practical work with such exact and philosophical descriptions as are found in Ganot's book. Practice without knowledge of theory is as bad as theory without practice. Prof. Reinold has added new matter, as well as revised the book, with the result that a comprehensive view is given of fundamental physical principles and relationships as now understood, suitable for elementary students of the science. The sections on magnetism and electricity have been greatly altered, and accounts of apparatus and machines which have ceased to be of interest have been omitted. Prof. E. A. Schäfer's "Essentials of Histology, Descriptive and Practical, for the Use of Students" has reached its sixth edition. The work has been greatly enlarged, the chief additions being in the text relating to the structure of the central nervous system. Many new illustrations have also been added. The volume is both an elementary text-book of histology and a practical manual giving students precise directions for the microscopical examination of the tissues.

THE additions to the Zoological Society's Gardens during the past week include two Cape Zorillas (*Ictonyx zorilla*) from South Africa, presented by Capt. W. B. White; a Red-footed Ground Squirrel (*Xerus erythropus*) from West Africa, presented by Mr. P. G. Knight; a Ruddy Finch (*Carpodacus erythrinus*) from Siberia, presented by Mrs. G. A. Way; two Mountain Ka-Kas (*Nestor notabilis*) from New Zealand, presented by Dr. W. H. Hornibrook; two European Pond Tortoises (*Emys orbicularis*), European, presented by Mr. E. C. Brown; two and three Moloch Lizards (*Moloch horridus*) from Australia, presented respectively by Mr. F. Richards and Mr. W. Nichols; a Common Viper (*Vipera berus*), British, presented by Mr. E. Ball; two Striated Babblers (*Aryga earlii*), a Roofed Terrapin (*Kachuga tectum*) from India, two Blyth's Nicobar Parrakeets (*Palaeornis caniceps*) from the Nicobar Islands, two Black Iguanas (*Metopoceros cornutus*) from the West Indies, a Royal Python (*Python regius*) from West Africa, a Corn Snake (*Coluber guttatus*) from North America, deposited; a Banksian Cockatoo (*Calyptorhynchus banksii*) from New South Wales, purchased; a Thar (*Hemitragus jemlaica*) born in the Gardens.

THE ROYAL OBSERVATORY VISITATION.

ON Saturday last the Board of Visitors made their annual visit to Greenwich, and the Astronomer Royal submitted his report for the past twelve months.

It cannot be said, however, that the weather was all that could be desired for such an occasion and for this time of the year.

The following is a brief *résumé* of the report:—

Transit-Circle.

With this instrument the usual observations have been made, the undermentioned table giving the details of the number involved.

Transits, the separate limbs being counted as one observation	11,133
Determinations of collimation error	303
Determinations of level error	663
Circle observations	9,666
Determinations of nadir point (included in the number of circle observations)	681
Reflection observations of stars (similarly included)	505

The number of stars observed in 1901 was 4,327.

Good progress seems to have been made in the observations of the reference stars for the astrographic plates, for which 10,000 stars are to be observed three times above and twice below pole—with the exception of about 1000 stars fainter than the ninth magnitude which cannot be observed below pole. A table giving the details of the progress up to date shows that for each of the five degrees of N.P.D. reckoning from the pole, 100, 90, 46, 46, and 45 per cent. respectively of the necessary observations have been secured.

The change in the method of adopting the azimuth error introduced at the beginning of 1900 has effected a satisfactory diminution of the small discordance in right ascensions taken on opposite sides of the pole.

The colatitude of the transit-circle as found from observations of about 581 stars in 1901 is 38° 31′ 21″·76, differing by −0″·14 from the adopted value. The values of this correction since 1897 are—

1897 ...	−0″·17	1900 ...	−0″·10
1898 ...	−0·15	1901 ...	−0·14
1899 ...	−0·14		

Very satisfactory progress has been made with the re-reduction of Groombridge's observations, the three years 1809, 1810 and 1811 with 10,500 observations of R.A. and N.P.D. having been finished since the last report. A catalogue of the positions of the stars in the *Berliner Jahrbuch* derived from Groombridge's observations from 1806 1810 was forwarded to Dr. Auwers for use in the preparation of his fundamental catalogue, and he found that a large increase in accuracy had been effected by the re-reduction.

The Altazimuth.

Through the frequent breaking of the spider lines in this instrument, the micrometer slides have been altered to reduce the span, and the result has been very satisfactory. The instrument has been used in the meridian in four positions as a reversible transit-circle for observations of sun, moon, planets, and fundamental stars, and also for observation of the Eros reference stars, and reference stars for Sir David Gill's heliometer observations of major planets. The total number of observations made was 6556.

Further determinations of the division errors have been completed, and these have been combined with the previous results and definitive corrections for division error deduced.

The Reflex Zenith Tube.

This instrument was, as is well known, originally designed by Sir G. B. Airy for the purpose of determining the constant of aberration by observations of γ Draconis, which passes very near the zenith of Greenwich, but after many years of observations it was found that the results for parallax of γ Draconis and aberration were anomalous, and an attempt was made in the years 1882 to 1886 by a long series of transits over the wires to refer these discordances to temperature effects, but without success. The observations of zenith distance of γ Draconis were, however, continued up to 1899, when they were dropped owing to the pressure of observations for the new Ten Year Catalogue. This instrument has, however, become of great importance, for Mr. Chandler has recently shown that the apparently anomalous results previously obtained are explained by the variation of latitude, and that this instrument is specially adapted to the determination of the amount of this variation.

It has therefore in consequence been decided to resume the observations of γ Draconis without delay, and to observe such other stars as passed near enough to the zenith and were sufficiently bright. By suitable modifications it has been found possible to increase the utility of the instrument, by which several other stars down to the seventh magnitude can be observed.

The 28-inch Refractor.

This instrument has been used throughout the year for micrometric measurements of double stars. The total number of double stars measured in the year is 382; of these 221 have components less than 1″·0 apart, and 120 less than 0″·5. The close pairs whose distance apart is less than 1″·0 have been measured on the average on three nights each, and the wider pairs on an average of two nights. The wider pairs consist of bright stars with a faint companion, of third companions to close pairs, and of stars of special interest.

In addition to the list of most difficult and interesting stars measured, it is stated that good series of measures have been obtained of κ Pegasi, δ Equulei, 70 Ophiuchi, and ζ Herculis. Capella also has been examined at every favourable opportunity.

Thompson Equatorial.

This instrument has been used chiefly for photographing Neptune and his satellite, and 52 measurable photographs were secured. With the 30-inch reflector long exposed photographs of Nova Persei were obtained, but unfortunately, owing to the object-glass of the guiding telescope not being quite firm in its cell, displacements during exposure occurred.

Astrographic Equatorial.

The photography for the Greenwich zone (Dec. + 64° to the Pole) having been practically completed, the work during the past year was directed to replacing such plates as were found to be inferior to the general standard. Four hundred and thirteen plates were taken, but of these fifty-seven were for various reasons rejected.

The report contains many details about the measurement of the plates, the counting of the number of stars, and various other preparations which would occupy too much space, but the following table may be given, as a good idea of the magnitude of the new work can be at once gathered:—

Limits of Declination.	Number of Stars Measured.	Number	Number in A.G.C.	A.G.C.
64°–65°	8,954	1,900	1,200	Helsingfors
65°–70°	49,210	7,782	3,700	Christiania
70°–75°	50,190	5,870	—	Dorpat
75°–77°	18,100	1,856	1,700	Kazan
77°–78° (oh. to 16h.)	5,430	613	420	,,

Spectroscopic and Heliographic Observations.

For the year 1901, Greenwich photographs have been selected for measurement on 149 days, and photographs from India and Mauritius (filling up gaps in the series) on 210 days, making a total of 359 days out of 365 on which photographs are at present available.

The proportion of days upon which the sun was entirely free from spots was 80 per cent. for the year 1901, and about the same proportion for 1902 to the date of this report. But the appearance of two considerable groups this year, and the high latitudes of the spots generally, are indications that the actual minimum is passed.

Magnetic Observations.

The variations of magnetic declination, horizontal force and vertical force, and of earth currents, have been registered photographically, and accompanying eye observations of absolute declination, horizontal force, and dip have been made as in former years. The regular determinations of magnetic declination, horizontal force, and dip have been made with the new declinometer, the Gibson deflection instrument, and the Airy dip circle mounted in the Magnetic Pavilion.

The principal results for the magnetic elements for 1901 are as follow:—

Mean declination ... ... 16° 26′·0 West.

Mean horizontal force ... { 4·0082 (in British units). 1·8481 (in metric units).

Mean dip (with 3-inch needles) ... 67° 6′ 5″.

These results depend on observations made in the new Magnetic Pavilion, and are free from any disturbing effect of iron.

The magnetic disturbances in 1901 have been small and few in number. There were no days of great magnetic disturbance and 8 of lesser disturbance.

Meteorological Observations.

The registration of atmospheric pressure, temperature of the air, and of evaporation, pressure and velocity of the wind, rainfall, sunshine and atmospheric electricity has been continuously maintained.

The mean temperature for the year 1901 was 49°·3, being 0°·2 below the average for the fifty years 1841–90.

During the twelve months ending 1902 April 30, the highest temperature in the shade (recorded on the open stand in the Magnetic Pavilion enclosure) was 87°·9 on July 19. The highest temperature recorded in the Stevenson screen in the enclosure was 86°·0, and in that in the Observatory grounds 87°·1 on the same day.

The lowest temperature of the air recorded in the year was 14°·3, on February 16. During the winter there were 52 days on which the temperature fell below 32°, a number slightly below the average.

The low temperature in February is the lowest temperature recorded in that month since 1895, when, on February 8, the minimum February temperature 6°·9 occurred.

The number of hours of bright sunshine recorded during the twelve months ending 1902 April 30, by the Campbell-Stokes instrument, was 1519 out of 4457 hours during which the sun was above the horizon, so that the mean proportion of sunshine for the year was 0·341, constant sunshine being represented by 1.

The rainfall for the year ending 1902 April 30 was 17·89 inches, being 6·65 inches less than the average of fifty years. The number of rainy days was 116. The rainfall has been less than the average in each year since 1894. The total deficiency of rainfall for the seven years ending 1901 December 31 amounts to 23·70 inches.

The remaining portion of the report deals with the printing and distribution of the Greenwich publications, the examination of chronometers, time-signals, &c.

A short reference is made to the re-determination of the Greenwich-Paris longitude, and to the expedition which went out to Sumatra and Mauritius to observe the total solar eclipse of May 18, 1901.

EVIDENCE OF A "SEICHE" ON A SCOTTISH LOCH.

WHILE engaged in the survey of Loch Trieg, Inverness-shire, on May 22, Dr. T. N. Johnston and Mr. J. Parsons, of the British Lakes Survey, observed what appears to be an undoubted *seiche*, *i.e.* a periodic variation in the level of a lake, considered by Prof. Forel, among others, to be due to sudden changes in barometric pressure, whilst others, again, consider them due to earth-movements.

The attention of Dr. Johnston was first drawn to the phenomenon by observing that certain small stones near the shore were covered and uncovered at regular intervals, the surface of the loch being perfectly calm at the time, and had been so during the day.

At a quarter to 9 p.m., a foot rule was placed vertically in the water and the surface level observed at intervals of one minute for forty minutes.

The results obtained confirmed the rougher observation that the surface of the water was undergoing slow oscillations.

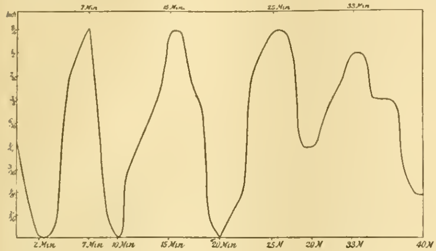
The amplitude of the wave proved to be $\frac{9}{16}$ inch, and the period, *i.e.* the time taken in rising from the lowest to the highest level and falling again, averaged 9·5 minutes.

Despite the smallness of the amplitude compared to that noticed on the Lake of Geneva and other lakes, the observers had no doubt that the movements were not due to surface ripples.

Loch Trieg is about six miles long and three-quarters of a mile wide, its longer axis lying nearly north and south. The survey of the loch is now completed, and a depth of 436 feet has been found within two miles of the southern extremity.

Should this variation of level prove to be a true *seiche* it will

be the first recorded on a Scottish loch, with the possible exception of a considerable rise and fall of the water of Loch Tay in 1784, which has been considered an example of this phenomenon.



The accompanying curve represents the variations in level observed on Loch Trieg, the ordinates representing periods of one minute and the abscissæ changes of $\frac{1}{16}$ inch in the level.

THE MINING STATISTICS OF THE WORLD.

OWING to the lack of uniformity and the want of completeness in the official statistics published in the countries where mining and quarrying are carried on, the compilation of the mineral statistics of the world is a task of extreme difficulty. The work is, however, carried out every year with conspicuous success by Prof. C. Le Neve Foster, F.R.S., in the Home Office general report on mines and quarries. The fourth part of this report, which has recently been issued, deals with the colonial and foreign statistics for 1900, and constitutes a work of reference of permanent value. It is impossible to imagine a more concise, a better arranged, or a more inexpensive collection of comparative mineral statistics. Last year's report was noticed at length in NATURE (April 4, 1901, p. 551), and as the general arrangement has been closely followed in the new issue, the nature of the work may best be called to mind by citing a few of the more important figures that furnish a comparison as regards labour, output and safety in various parts of the world.

The following figures are given for the world's mineral production in 1900:—

	The World.	British Empire.	United Kingdom.	United States.
Coal, metric tons ...	767,636,204	247,938,725	228,794,919	244,901,839
Iron, metric tons ...	40,427,435	4,987,641	4,741,835	14,014,475
Copper, metric tons..	534,735	41,456	777	275,008
Lead, metric tons ...	787,841	73,203	24,755	245 757
Tin, metric tons ...	80,643	51,624	4,336	—
Zinc, metric tons ...	446,373	13 417	9,211	112 419
Petroleum, metric tons...	18,553,950	241,344	—	7,485,579
Salt, metric tons ...	12,572,076	3,131,029	1,891,217	2,650,075
Fine gold, kilogrammes	393,196	188,491	415	119,913
Fine silver, kilogrammes	5,874,284	582,932	5,936	1,862,829

The figures given show that although Great Britain has had for a second time to give to the United States the first place in the production of coal, the British Empire as a whole is still the largest producer of solid mineral fuel, yielding nearly one-third of the world's output. The gold output of the British Empire is also the largest, and will probably increase. The United States, however, comes first in the production of the ores of copper, iron and lead. The German Empire, with 153,350 tons, is the largest zinc producer, and Russia, with 9,827,822 tons, is the largest producer of petroleum. Thanks to Tasmania and the Federated Malay States, the British Empire possesses the most productive deposits of tin ore.

The comparison of the figures relating to labour gives some interesting results. In 1900 the number of persons employed in the mines and quarries of the various countries was as follows:—The world 4,475,355, the British Empire 2,883,200, the United Kingdom 908,412, the United States 506,830 (returns incomplete), Germany 733,683, France 309,815, Belgium 171,467, Austria-Hungary 226,330, Russia 286,983, Italy 102,728, and Japan 119,667.

As regards the safety of its miners, Great Britain takes a high place. The number of fatal accidents in collieries per 1000 persons employed was as follows in the year under review:—Great Britain 1·29, Germany 2·19, Austria 1·08, France 1·42, Belgium 1·05, and United States 3·29 In the United States the death rate, both in bituminous coal mines and in anthracite mines, is considerably higher than in the United Kingdom. The rapid extension of machine mining in the United States is very remarkable. In 1891, it is stated, only 6·7 per cent. of the output of bituminous coal was obtained by the aid of coal-cutting machinery; in 1900 the proportion had risen to 25 per cent.

The abundant and accurate references to current literature given in footnotes form a very valuable feature of the report. Hundreds of books, pamphlets and newspapers in various languages have been consulted, and much interesting information derived from them is recorded.

In one or two cases, statements are quoted that are, perhaps, open to criticism. For example, the statement that Dr. Carl Peters gives many excellent reasons for supposing that Macombe's country, south of the Zambesi, in Portuguese East Africa, is the Ophir of Scripture hardly gives a correct impression of the prolonged controversy as to the site of Ophir. Moreover, so competent an authority as Prof. A. H. Keane has recently decided in favour of the south of Arabia. Ophir, he shows, was not the place at which the gold, to which it gave its name, was found; it was the emporium to which the products of the east and south were brought and from which they were distributed. Another statement which is not strictly accurate is that the yield of the oil wells of the United States almost equals that of all the rest of the world put together. In view of the fact that the Russian output is given as 2,342,243 metric tons more than that of the United States, this statement is somewhat misleading.

It is interesting to note the effect of the war in South Africa on the mineral production. In the Transvaal the output of gold was small; and in Natal until March 1900 all the collieries were in the possession of the invaders, the output of coal being consequently comparatively small. In the Orange River Colony mining was carried on under very great difficulties and upon a very reduced scale. In Cape Colony the siege of Kimberley and the war generally interfered greatly with mining. In Rhodesia, however, the output of gold showed a steady increase, and the future prospects of the industry have been much brightened by the discovery of rich deposits of coal. In the Wankie coalfield alone, which lies 190 miles north-west of Buluwayo, the workable seams are considered capable of yielding 1500 million tons of coal.

It is impossible within the limits of this notice to refer to all the points of interest suggested by the report; but enough has been said to show to how wide a circle of readers this invaluable work of reference appeals. B. H. B.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—An examination for one geographical scholarship of the value of 60*l*. will be held on October 14. Candidates, who must have taken honours in one of the final schools of the University, should send in their names to the Reader in geography not later than October 1. The scholar elected will be required to attend the full course of instruction at the school of geography during the academic year 1902–1903, and to enter for the University diploma in geography in June, 1903.

CAMBRIDGE.—The Mathematical Tripos list, Part i., was published on June 10. The senior wrangler this year is Mr. E. Cunningham, St. John's College. Mr. F. Slator, also of St. John's, is the second wrangler.

The Rede lecture was delivered in the Senate House on June 10 by Prof. Osborne Reynolds, F.R.S., the subject being "On an Inversion of Ideas as to the Structure of the Universe."

The honorary degree of Doctor of Science has been conferred upon Principal Rücker, F.R.S., and Sir H. H. Johnston.

SOME remarks upon the subject of medical education were made on June 5 by Mr. Asquith, M.P., at the festival dinner of the London Medical Graduates' College and Polyclinic. He expressed the opinion that in all the professions England compares most unfavourably with America, Germany and most other countries in the lack of provision for the continuation of education in its technical and applied forms after the ordinary term of academic life has been reached. Medicine, which is at the same time a science and an art, is every year receiving vast accumulations of new observations and new experiments which must profoundly modify the conception of both the theory and the treatment of disease. Adequate provision must therefore be made for post-graduate research if scientific knowledge of disease is to be increased.

THE thirty-seventh annual programme just received from the Massachusetts Institute of Technology contains a full statement of the courses of instruction at this well-known institution and a register of the alumni, the whole publication forming a prospectus of more than four hundred pages. The Institute offers thirteen separate courses in applied science, each of four years' duration. The laboratories of the Institute are numerous and extensive; their equipment is correspondingly ample, and is kept well up to the rapid advances in technical practice. Provision is made for exact general training in the problems of physics and chemistry for highly specialised work in these and other sciences, and for engineering tests and processes on a practical scale. The large number of students at the Institute, no less than the increasing demands of modern scientific education, have made necessary new laboratories for the departments of electrical engineering and physics. Buildings of a most complete kind have been designed for these purposes, and their erection will be begun early in the spring of 1902. They will cost, with their equipment, between 400,000 dollars and 500,000 dollars.

THE second volume of the report of the United States Commissioner of Education for the year 1899-1900 is a closely printed book of 1368 pages. The series to which it is the latest addition does for educationists what the annual reports of the Smithsonian Institution do for men of science. There is to be found brought together in these portly volumes everything of importance which has taken place, not only in American education, but in that of all the great countries of the world. The plan adopted in the Smithsonian reports, of reprinting valuable contributions collected from various sources, is followed in the volume before us, with the result that many of the addresses and essays by English educational authorities, to which attention has been directed from time to time in these columns, are here to be found printed in full. The prominence given to the higher grades of education shows very clearly that, while making strenuous efforts to perfect their systems of primary and secondary education, the authorities in the States are not losing sight of the paramount importance of technical and university work. Chapters are given to "Institutions for Higher Education," "Professional Schools," "Agricultural and Mechanical Colleges," and "Commercial and Business Schools." Though few teachers can find time to study the reports brought out from year to year, much of the information contained in the volumes is of permanent value and will often be referred to by students of education.

SEVERAL points in the revised regulations for matriculation at the University of London are worthy of notice. The list of subjects has already been given (p. 69). There are only two obligatory subjects—English and elementary mathematics. Latin is optional with one of several sciences; and two other subjects have to be selected from a list of twenty branches of knowledge. Under the new regulations, therefore, it will be possible to matriculate at the University of London, and to proceed to a degree, without taking any science subject. The short syllabus of mathematics shows the influence of the reformer. Under arithmetic mention is made of the metric system, contracted methods, approximations to a specified degree of accuracy, and practical applications. Algebra includes graphs of simple rational integral algebraic functions. In geometry the subjects of Euclid I.-IV. will be taken, but Euclid's proof will not be insisted upon. The short syllabuses of optional sciences are prefaced by the remark "The examinations in science shall aim at ascertaining whether candidates possess a knowledge of fundamental scientific methods, acquired by observation of nature or by a simple course of experiment in physical measurement, or by the investigation of simple problems and commonly occurring phenomena illustrating natural laws." In all the science subjects the questions set will have regard to the conditions under which these subjects may best be experimentally taught in schools.

A SERIES of resolutions in regard to the Government Education Bill were adopted at a special general meeting of the Association of Technical Institutions on May 29 The resolutions are to the following effect:—(1) That the Association approves the general principles upon which the Government Education Bill is based, and strongly urges the Government to pass the Bill in the present session of Parliament. (2) That the new local authorities should be responsible for all grades of education in their districts, and that proper educational coordination would be seriously and unnecessarily hindered if this principle were not adopted; the Government is therefore urged to amend the Bill by deleting the clauses making it optional for the County and Borough Councils to undertake the supervision of elementary education. (3) That the Government should make compulsory the application to the purposes of higher education of the residue under the Local Taxation (Customs and Excise) Act, 1890. (4) That, insomuch as the Local Authorities constituted by the Bill will have to make good the deficiencies in elementary and general secondary education, as well as to support and improve technical education, and will be obliged to raise increased rates in order to do this efficiently, it is feared that in many cases these authorities will shrink from the necessary expenditure unless encouraged by increased aid from the national exchequer. The Government is therefore asked to promise to provide larger sums for educational purposes. (5) That there should be no statutory limit to the amount to be expended on higher education. (6) That the majority of the Education Committee should be appointed by and from the council of the County Council or County Borough Council. (7) That any attempt to alter the provisions of the first two sections of clause 18 of the Education Bill will be resisted. (8) That London may receive attention early next year, and that it would be unwise to depart from the general principles of the present Bill in the case of the metropolis.

THE ideal University for London, described by Prof. E. H. Starling, F.R.S., in the Foundation Day oration delivered at University College, London, on June 5, was much the same as that advocated in these columns on several occasions. Prof. Starling said that in the University there would be a centre in each of the four quarters of London. Each of those centres would be in so far a complete University in that it would be a place for study and research in all branches of knowledge and would be a community of teachers and scholars. The local business affairs of each centre would be under the control of a committee or council appointed by the senate of the University, but containing representatives of the local body of professors. All those centres would be but parts of this University, with common aims, with similar curricula, and the same standard of examination. The senate of the University, which would contain representatives from all centres, would be responsible for the appointment of the local governing bodies and would keep in its own hands the power of appointing and dismissing professors. It would be possible in that way to provide for the training of 10,000 students within the University of London, and to ensure the freedom of teaching and research and the living contact of each student with men of different ideals and modes of thought, which were the most valuable factors in a University training. Such a University could not be founded without the possession of adequate means. Each centre would necessitate the erection of buildings at a cost of about 500,000*l.* on ground covering from five to ten acres. For a moderate endowment of its professorships and the maintenance of its laboratories a yearly income of 50,000*l.* should be provided in addition to the income from students' fees, which might amount to another 30,000*l.* These might seem large sums to those who were ignorant of the money spent abroad by the State on Universities or of the income which was available from ancient endowments at Oxford and Cambridge. The united income of of the colleges at Oxford was 330,000*l.* a year, and at Cambridge nearly 300,000*l.* a year. The yearly Government grant to the University of Strasburg, with only 1000 students, was 50,000*l.* He was convinced that there would be no difficulty

in raising those amounts in London, either by the generosity of its rich men or by grants from public funds, if only those interested in the making of a University would combine their efforts towards a common end. The task was rendered easier by the fact that in the building of the University they could utilise for University purposes in London many of the buildings and endowments already existing, and it was in the hope of inaugurating a common movement in that direction that University College had declared itself ready to be incorporated in the University.

SCIENTIFIC SERIALS.

Transactions of the American Mathematical Society, vol. iii. No 2, April.—E. W. Brown, on the small divisors in the lunar theory.—J. W. Young, on the holomorphisms of a group. This deals with non-abelian groups such that there is a one-one correspondence between the elements of the group and their αth powers.—F. R. Moulton, a simple non-desarguesian plane geometry. A simpler system than that given by Hilbert in his "Grundlagen der Geometrie," with a proof that his axioms I. 1–2, II., III., IV. 1–5, V. are fulfilled, while Desargues' theorem is not true.—M. Bôcher, on the real solutions of systems of two homogeneous linear differential equations of the first order. Propositions relating to $y' = Py - Qz$, $z' = Ry - Sz$ analogous to those given by Sturm for $y'' + py' + qy = 0$.—Charlotte A. Scott, on a recent method of dealing with the intersections of plane curves. The method in question is that of F. S. Macaulay (*Proc.* L.M.S. vols. xxxi., xxxii.).—E. V. Huntington, a complete set of postulates for the theory of absolute continuous magnitude. Six postulates are laid down, and shown to be consistent and independent of each other. A short paper by the same author follows, on the postulates for the theories of positive integral and positive rational numbers.

Bulletin of the American Mathematical Society, second series, vol. viii. No. 8, May.—C. J. Keyser, concerning the angles and the angular determination of planes in 4-space.—D. R. Curtiss, note on the sufficient conditions for an analytic function.—Reviews:—Scheffer's "Theory of Surfaces," by J. M. Page; "Some Recent Books on Mechanics," by E. B. Wilson; "The Galois Theory in Burnside and Panton's Theory of Equations"; and shorter notices.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 20.—"On a Peculiarity of the Cerebral Commissures in certain Marsupialia, not hitherto recognised as a Distinctive Feature of the Diprotodontia," by Prof. G. Elliot Smith, M.D., Ch.M. Communicated by Prof. G. B. Howes, F.R.S.

It has been known for a considerable time that some of the fibres of the ventral commissure of the cerebrum in certain marsupials, instead of passing bodily into the *external* capsule, form an aberrant bundle, which associates itself with the *internal* capsule so as to reach the dorsal area of the neopallium by a shorter and slightly less circuitous course.

This peculiarity has been recorded by the late W. H. Flower, by Johnson Symington and by Theodor Ziehen in Macropus, Phascolomys, Aepyprymnus, Phascolarctus and the Derbian Wallaby, and in Phalangista by myself.

In 1894 I showed that while in the monotreme and Perameles the common mammalian relationship of the ventral commissure to the external capsule was found to obtain, in Trichosurus and Macropus some fibres of the ventral commissure were found to pursue the aberrant course indicated above. It was perhaps not unnatural to suppose that the increased size of the neopallium in these two genera was wholly responsible for the presence of this aberrant bundle; for it seemed that since the commissural fibres of the neopallium had become too abundant to be wholly accommodated by the path provided by the external capsule, they, so to speak, had overflowed into the internal capsular route.

Upon examining later a much larger series of marsupials, I soon became convinced that the explanation of the causation of this peculiarity which I then suggested could not be regarded as alone sufficient. I found the aberrant bundle in all members of the genera Macropus, Halmaturus, Hypsiprymnus, Dendrolagus, Trichosurus, Petaurus, Phascolarctus and Phascolomys, quite irrespective of the size of the brain and extent of the neopallium; but I sought it in vain in Perameles, Sarcophilus, Dasyurus, Sminthopsis, Didelphys, Myrmecobius, and Notoryctes, even though many of these genera possess larger brains than some Diprotodonts.

These facts seemed to suggest that the aberrant bundle was a distinctive feature of the Diprotodont marsupials, and it appeared that the crucial test of this hypothesis would be afforded by the brain of Thylacinus, which, although that of a Polyprotodont, is almost, if not quite, as large as the brain of the largest Macropod. I accordingly submitted the cerebrum of Thylacinus to the test, and found no trace of the aberrant bundle, wherefore it is clear that the presence of this aberrant fasciculus of the ventral commissure is distinctive of the Diprotodontia.

The most pronounced growth tendency in the earliest mammals must have been an enormous increase in extent of the neopallium, for while at the beginning of the Eocene period this was almost as insignificant as it is in the Reptilia, in most recent mammals it attains a bulk which far exceeds that of the whole of the rest of the nervous system. This sudden expanse of the neopallium would lead to the development of an enormous mass of fibres which must find some outlet from the pallium; and there are only three possible routes for commissural fibres of the neopallium to the mesial plane. There is first the external capsule, which chiefly consists in all mammals of such fibres passing to the ventral commissure; we find the second route in the path mapped out by the internal capsule from the dorsolateral neopallial area to it; and the third route can only involve the invasion of the alveus of the hippocampus.

All the neopallial commissural fibres in the Polyprotodontia and *some only* of these in the Diprotodontia and Eutheria follow the first route. The commissural fibres, which spring from the dorso-lateral region of the neopallium in the Diprotodontia, crowded out of the first route pursue the second. In the Eutheria the neopallial commissural fibres from the dorso-lateral region of the hemisphere forsake both the first and second routes and invade the alveus, so as to form a new dorsally situated neopallial commissure, which is the corpus callosum.

This hypothesis of the origin of the corpus callosum I have previously stated and discussed; and I refer to the matter now merely to point out that the same determining cause which in the Eutheria calls the "corpus callosum" into being is probably functional in bringing into existence the "aberrant bundle" in the Diprotodontia.

The development of any such commissural mass as the corpus callosum of the more highly organised Mammalia in the position occupied by its homologous fibres in the monotremes and marsupials would cause the most profound disruptions of the corpus striatum, optic thalamus, and the basal region of the brain, and the complete disorganisation of its whole; and hence the new course taken by its fibres in the Eutheria.

May 15.—"Cyanogenesis in Plants. Part II.—The Great Millet, *Sorghum vulgare*," by Wyndham R. Dunstan, M.A., F.R.S., Director of the Scientific Department of the Imperial Institute, and T. A. Henry, D.Sc. Lond.

May 29.—"On the Structure of the Gills of the Lamellibranchia," by Dr. W. G. Ridewood. Communicated by E. Ray Lankester, M.A., F.R.S.

This paper records the results of an investigation undertaken at the instance of Prof. E. Ray Lankester, F.R.S., and carried on under his supervision. 215 species of Lamellibranchia, belonging to 118 genera, were examined. The results demonstrate that although the minute structure of the gill, like the grosser structure, cannot be taken as a criterion of genetic affinity, three main types of structure can be recognised, representing apparently three grades of complexity.

The first type is distinguished by the mutual freedom of the gill leaflets into which the embryonic gill papillæ expand. In the other two types the embryonic papillæ elongate into filaments, which are held in juxtaposition by interlocking cilia, or by horizontal bars of cellular tissue.

Evidence is produced to show that Pelseneer's order Pseudolamellibranchia is based largely on a misconception of the relative value of the flatness or plication of the gill lamellæ, and the presence or absence of principal filaments.

In the family Solenidæ particularly it is shown that different species and subgenera of the same genus may have their gill

lamellæ flat or plicate, and the filaments all of one kind or with enlarged principal filaments at intervals.

Avicula argentea proved to be a form of supreme interest, in that both ciliated discs and organic interfilamentar junctions are present.

Anomia aculeata is of no less interest, since it differs from the other species of Anomia examined, and resembles the rare Dimya, in that the gill filaments are not reflected.

The gills of Vesicomya and Euciroa, which were said by Dall to exhibit close resemblances with those of the Protobranchia, prove to be of the reticulate type.

The forms included by Pelseneer in his order Septibranchia are, at least so far as can be judged by their branchial organs, degenerate molluscs of the Lyonsiella type, and the suppression of the Septibranchia as a distinct order is advocated.

Entomological Society, May 7.—The Rev. Canon Fowler, president, in the chair.—Mr. H. W. Shepheard-Walwyn exhibited a gynandromorphous specimen of *Anthocaris cardamines*, taken near Winchester in 1899. The left side was that of a normal ♂, the right that of a normal ♀, with the exception of a splash of orange pigment on the underside of the primary.—Mr. H. Goss exhibited two ♂ specimens of *Saturnia carpini* from Essex, bred on whitethorn, and three ♂♂ of the same species caught in Surrey by the aid of bred (virgins) ♀♀. He remarked that as a rule bred specimens were smaller than wild, but the bred Essex specimens were much larger than those captured in Surrey. The Essex specimens were light in colour, while the Surrey specimens were not only much smaller in size, but very dark, probably because their larvæ had fed upon Erica or Calluna.—Colonel C. Swinhoe announced the emergence of *Cossus ligniperda* in the Zoological Society's Gardens from a pupa received in a piece of wood from South Africa, and said that it was remarkable that the species should have been introduced there and then brought back to Great Britain.—Prof. E. B. Poulton exhibited two Euplœinæ captured in Fiji by Prof. Gilson, and presented by him to the Hope Department. The species, which belonged to the different genera Nipara and Deragena, bore the closest superficial resemblance to each other, affording an interesting example of Müllerian or synaposematic likeness.—Prof. Poulton also exhibited several specimens of *Smerinthus populi* which had been exposed during the pupal stage to the intense heat of July, 1900. In consequence of this "forcing," the moths emerged towards the end of that month, and were markedly different in colour from the normal, being much paler in tint with less distinct markings, and the red of the hind wings of a very different shade.—The Rev. A. E. Eaton exhibited drawings illustrating the wing of *Pampterinus latipennis*, Etn. MS., a remarkable dipterous fly of the family Psychodidæ, from New Guinea, in the collection of the Hungarian National Museum, Budapest.—Prof. L. C. Miall, F.R.S., contributed a paper on a new Cricket of aquatic habits found in Fiji by Prof. Gustave Gilson, Dr. T. A. Chapman a paper on asymmetry in the males of Hemarine and other Sphinges, and Mr. E. Meyrick a paper on Lepidoptera from the Chatham Islands.

Geological Society, May 14.—Prof. Charles Lapworth, F.R.S., president, in the chair.—Pliocene glacio-fluviatile conglomerates in Subalpine France and Switzerland, by Mr. Charles S. Du Riche Preller. In the present paper the author describes a number of further deposits of typical Deckenschotter conglomerate recently examined in the Aare and Rhine valleys, near the confluence of those rivers, and shows that these, in conjunction with the Deckenschotter deposits of the Zurich district, indicate the almost unbroken outline of a Subalpine Deckenschotter cone, which extended from the base of the Alps in a north-westerly direction over a distance of about 25 miles, and was formed by the waters of the retreating Rhine (western) glacier and its affluents on a Molasse plateau, the upper and lower ends of which were at the contours of 900 metres and 500 metres respectively. He further describes a series of Deckenschotter deposits examined in the Rhone valley between Lausanne and Lyons, including the extensive plateau of the Dombes, east and north of Lyons, composed of marine marl overlain by the characteristic *conglomérat ferrugineux*, which some French geologists still regard as pre-Glacial and others as Quaternary, but which is typical Deckenschotter, and in the full acceptation of the term an *alluvion des plateaux*. The deposits thus described afford proof of the existence, in Upper Pliocene times, of an extensive alluvial cone about 100 miles in length, which reached from Lausanne (probably even from the base of the Alps) to Lyons, and was formed by the waters of the retreating Rhone and Arve glaciers on a Molasse-and-marl plateau, the altitude of which above sea-level was 800 metres near Lausanne and 300 metres near Lyons. From this concurrent evidence in northern Switzerland and in the Rhone valley, the author is led to conclude that at the time of the deposition of those alluvial cones, the principal Subalpine valleys and lake-basins could not as yet have existed in their present form or depth, and must have been from 100 to 200 and 400 metres higher; and that the Subalpine valleys were eroded to their present depth in the course of the inter-Glacial period—now recognised to have been of very long duration—between the Pliocene and the Middle Pleistocene (or maximum) glaciations, and that the Subalpine lake-basins were formed in the same period by the contemporaneous action of fluviatile erosion and of a zonal settling along the base of the Alps after these had been raised by horizontal pressure.—Overthrusts and other disturbances in the Braysdown Colliery (Somerset), and the bearing of these phenomena upon the effects of overthrust-faults in the Somerset coalfield in general, by Mr. F. A. Steart. This coalfield, although covered by comparatively undisturbed Secondary rocks, is in part the most disturbed and contorted of those known and worked in the United Kingdom. The "Radstock Seams" of the Upper Coal-measures at Radstock are traversed by a huge "overlap fault," which thrusts them forward for a great distance; this runs nearly east and west, and has parallel to it two smaller overthrusts. In one of them the coal at first dips towards the thrust, then it thickens from 2 to 6 or 8 feet, next it becomes inverted, and eventually regains its former character. The continuity of the coal has been proved in the case of three of the coal-veins. As there is practically the same sequence of strata on both sides of the fault, it is concluded that the "overthrusts" did not take place until all the coal-seams of the Radstock series had been deposited.

Royal Microscopical Society, May 21.—Dr. Hy. Woodward, F.R.S., president, in the chair.—Mr. T. W. Ersser brought for exhibition a new acetylene illuminator for the lantern which he said would give a light of 300 candle power for three hours at a cost of ninepence.—Mr. D. J. Scourfield gave an exhibition of freshwater Entomostraca. He confined himself to the Cladocera and to the illustration of their various habits of life and powers of movement, ranging from the free-swimming forms found in lakes to those which simply crawled in or on the mud. Most of the living specimens were shown in live boxes, but one specimen was attached to a pin by means of a small drop of sealing wax varnish, which permitted the creature to carry on all its movements without getting out of the field of view. A number of living and mounted specimens were exhibited under microscopes.

CAMBRIDGE.

Philosophical Society, May 19.—Prof. Macalister, president, in the chair.—Some observations on protandry and senescence in Flabellum, by Mr. J. Stanley Gardiner.—A note on the dispersive power of running water on skeletons: with particular reference to the skeletal remains of *Pithecanthropus erectus*, by Mr. W. L. H. Duckworth. This communication consisted in an account of the distribution of the bones of the skeleton of a horse along the bed of a mountain stream in North Wales. It was observed that the distance over which distribution had occurred was at least one hundred and fifty-three feet. This observation was applied to the case of the fossil bones found in a river bank in Java and described by their discoverer as those of an animal more closely allied to man than is any known ape and called *Pithecanthropus erectus*. One objection to this description rests on the fact that the two bones on which our knowledge of that animal is based were separated by a distance of nearly forty-nine feet, though on the same level. The present observation goes to show that this objection is not valid, inasmuch as the larger bones here mentioned were distributed over a considerably greater distance than forty-nine feet, by a stream of small dimensions.—The coral reefs of Zanzibar, by Mr. C. Crossland. The paper shows that the fringing reef which extends along the whole eastern or ocean side of Zanzibar Island is not due to recent growth, but is the result of the eroding action of the sea upon the margin of the mass of elevated coral limestone which forms this side of

the Island. The edge of the flat thus formed is protected by living organisms from further erosion, though no addition to the reef results for them. The only recently formed rocks which occur are (1) coral and nullipore growths in the boat channel, (2) the beginnings of new reefs round certain shoals and islands off the west coast. Zanzibar thus affords a comparison with the Bermudas, where the same cause, marine erosion, acting upon a differently formed but physically similar limestone, has produced a semblance, not merely of fringing reefs, but a "pseud-atoll."—On an attempt to detect the ionisation of solutions by the action of light and Röntgen rays, by Mr. J. A. Cunningham.—On the influence of molecular attraction on collisions, by Mr. O. W. Richardson. This paper is an extension of the method used by Sutherland (*Phil Mag.* [5] xxxvi. p. 507) to explain the variation of vicosity of gases with temperature. Its use is further illustrated by calculating the rate of recombination of X-ray ions in air.—On the influence of ultra-violet radiation on the discharge in a vacuum tube having a polished zinc electrode, by Mr. W. C. Baker.—On the variation of double refraction in strained glass with wave-length, by Mr. L. N. G Filon.

EDINBURGH.

Royal Society, May 19.—Prof. Duns in the chair.—Mr. R. C. Mossman, in a note on the meteorological conditions accompanying "föhn" and up-bank thaws in Glen Nevis, gave an account of some observations he had made last winter, when he had carried out a series of hourly readings of temperature, pressure and humidity at the head of Glen Nevis. On certain occasions he found the air in the glen to be much warmer and drier than at Fort William, the barometer also being higher. The barometric gradient was from east to west, so that the air was drawn away from the base of the mountain and replaced by air from higher altitudes. Excursions were made on the surrounding hills during the föhn, which was found to extend to a height of 2000 feet. The weather was very fine, but a somewhat similar phenomenon was found in rainy weather. A number of cases of up-bank thaw were also described. In these the temperature, which normally falls as the height increases, is higher at the higher altitudes. For example, on February 1, at 10 a.m., the temperature on the top of Ben Nevis was 20°.4 F. higher than in the Glen. The phenomenon was explained as due to the sliding of the cold air down the hillsides into the valleys, which, because of the freer radiation during intense frost, become colder than the hillsides.—Mr. Mossman also read a paper on the meteorology of Edinburgh, in which he brought down his previously published historical record to the end of the last century. The present communication covered the ten years from 1891 to 1900. The paper also dealt with epidemics in relation to the weather from 1497, and with wheat prices from 1801.—Prof. A. Smith, in a paper on the influence of varying temperature and pressure on the vapour density of calomel vapour, sought to distinguish whether the vapour of calomel under ordinary conditions contains $HgCl$ or Hg_2Cl_2 in addition to mercury and mercuric chloride, the presence of which has been demonstrated definitely although their quantity is unknown.—Two communications were also received from Dr. Thomas Muir, on vanishing aggregates of secondary minors of a persymmetric determinant, and on the theory of orthogonants in the historical order of its development up to 1854.

DUBLIN.

Royal Dublin Society, May 21.—Prof. T. Johnson in the chair.—Dr. W. E. Adeney read a paper on the chemistry of respiration in bacteria. The experiments described in this communication have been made with a view of gaining some information as to the actual course of respiration within the protoplast. The course of physiological oxidation has been studied by determining the atmospheric oxygen consumed, the carbon dioxide formed, and also the ammonia formed, during different stages of fermentation, from commencement to completion, in very dilute unsterilised distilled water solutions of asparagine, of albumose and of Rochelle salt, these substances being selected on account of the simple nature of the result, of their aërobic fermentation. The asparagine was found to be quickly hydrolysed during the earlier stages of the fermentation into ammonia and aspartic acid, the last-named substance then undergoing complete oxidation in regular gradations, the final amounts of carbon dioxide and ammonia formed accounting for about 70 per cent. of the carbon and 85 per cent. of the nitrogen originally present in the asparagine. The course of oxidation of the albumose took place in approximately regular gradations throughout the course of fermentation, and is graphically represented by an approximately straight line, both when the carbon dioxide formed is taken against the oxygen consumed and when it is taken against the ammonia which is also formed in the process of oxidation. The course of oxidation of the asparagine, after being hydrolysed into aspartic acid, is also graphically represented by an approximately straight line, whether the carbon dioxide formed be taken against the oxygen consumed or against the ammonia formed. The oxidation of the Rochelle salt occurs in two separate and approximately equal steps, and its course in each takes place in equal gradations, since in both it is graphically represented by straight lines. The quantity of salt completely oxidised amounts to about 75 per cent. of the whole. A similar proportion of the albumose was also found to be completely oxidised during its fermentation. It appears to the author as most probable from the results here referred to, and from others obtained from his experiments on dissolved gases and fermentative changes, already published in the *Transactions* and *Proceedings* of the Society, that the course and nature of physiological oxidation under aerobic conditions in solutions of similar composition will be found to be similar in nature for all unicellular organisms, and will only vary in degree as the supply of energy required for vital activity may vary for different organisms.—Prof. J. Joly, F.R.S., described some experiments on the influence of light on sedimentation.—Mr. Richard J. Moss gave an account of a deposit from a steam boiler fed with the water of the river Vartry with which Dublin is supplied.

PARIS.

Academy of Sciences, June 2.—M. Bouquet de la Grye in the chair.—On Abelian functions with complex multiplication, by M. G. Humbert.—The experimental study of the dissociation of the constitutive elements of the energy used in motors employed in the production of positive work, by M. A. Chauveau. A comparison of the energy losses in the production of a given amount of work in the cases of inanimate and animate motors.—The mean distribution of the stellar images in the negatives of the map of the sky obtained at the Observatory of Toulouse, by M. B. Baillaud. The examination of forty-two negatives taken at Toulouse gave results agreeing with those recently published by Turner from observations made at Oxford.—The viscosity in the neighbourhood of the critical point, by M. P. Duhem. Theoretical considerations are developed which appear to render a satisfactory account of all the peculiarities presented by fluids in the neighbourhood of the critical point.—Magnetic work round the central *massif* of Madagascar, by M. P. Colin. The magnetic declination was determined at thirty-five stations, the inclination at twenty-four, and the intensity at twenty-five, the results being given in a table.—On the cranial characters and the affinities of Lophiodon, by M. Ch. Deperet.—On the constitution of nebulæ, by M. Charles Nordmann. It has recently been shown by the author that the hypothesis of an electromagnetic radiation from the sun is sufficient to explain in a simple manner many celestial and meteorological phenomena. The same hypothesis may also be extended to explain some of the phenomena exhibited by nebulæ.—Connection between the photographs of the solar corona taken at the total eclipse of May 18, 1901, and those of the entire solar chromosphere obtained on the same day at Meudon, by M. H. Deslandres. Among the results of the expedition to Sumatra organised by the Lick Observatory for the observation of the total eclipse of May, 1901, was a negative showing a good image of the solar corona. From this it appeared that in the latitude of 9°, in the north-east quadrant, there was a disturbance of the coronal rays special to this region. A comparison of this photograph with ordinary negatives of the solar photosphere taken at Greenwich and in India showed no sign of spot or even of special activity of the surface on May 17 and 18, but on May 19 a spot appeared in latitude 9°, in the north-east quadrant, which was remarked by Perrine as being intimately connected with the coronal disturbance. An examination of the negatives obtained at Meudon at the same time completely confirms this view.—On differential equations of the second order which admit of a finite continuous group of algebraic transformations, by M. Obriot.—On two problems in geometry, by M. Servant.—On a method of comparing motors of different powers, by M. Max. Ringelmann. The amount of fuel used per hour in internal

combustion engines is regarded as a linear function of the power of the engine. Considerations deduced from this formula were applied to the discussion of the relative merits of alcohol motors at a recent competition.—On the specific inductive capacity of dielectrics at low temperatures, by MM. Jacques Curie and P. Compan. The soakage effects in glass tend to disappear at low temperatures. The dielectric capacity varies as a linear function of the temperature, the temperature coefficient being determined for glass, ebonite, mica and quartz.—The influence of the voltage in the formation of ozone, by M. A. Chassy. When the voltage is sufficiently high for the discharge to take place, the production of ozone is proportional to the square of the difference of potential which exists between the armatures.—Contribution to the study of the magnesium light. Measurement of the speed of combustion and the chronophotography of the light, by M. Albert Londe. It has usually been considered that the average time of exposure in taking a photograph by means of a magnesium flash light powder was of the order of 1/100 of a second. Exact measurements, however, have shown that the time is much slower, varying from ¼ to 1/25 of a second and averaging 1/10 of a second. This time is too great to permit of photographs of rapidly moving objects being made in this way.—Stereoscopic examination in radiology, and illusions in the appreciation of relief, by M. Th. Guilloz.—On the electrocapillary properties of organic bases and their salts, by M. Gouy.—Preparation of the anhydrous chlorides of samarium, yttrium and ytterbium, by M. Camille Matignon. The anhydrous chlorides of ytterbium and samarium were obtained for the first time by heating the hydrated salts in a current of hydrochloric acid gas.—Ammoniacal copper oxide, by M. Bouzat. Starting from copper hydrate and ammonia, the cuprammoniacal base is formed with a slight disengagement of heat, the base formed being much stronger than ammonia.—The action of monochloracetoacetic ester upon diazobenzene chlorides, by M. G. Favrel. The reaction is similar to that described by Japp and Klingemann for methylacetoacetic and ethylacetoacetic esters. The acetyl group is eliminated and hydrazones are formed.—On some salts of benzylamine, by M. René Dhommée. A description of the preparation and properties of the nitrate, sulphate, borate, chromate, oxalate and benzoate of benzylamine.—On *Staurosoma parasiticum*, by MM. M. Caullery and F. Mesnil.—Bacterial parasites of the intestine of the larvæ of *Chironomus plumosus*, by M. Louis Léger.—The quantitative variations of plankton in the lake of Geneva, by M. Emile Yung.—On the presence of osseous tissue in certain fishes of the Palæozoic strata of Canyon City, Colorado, by M. Leon Vaillant. In the fauna of these strata, which is one of the oldest known, not only are there undoubtedly vertebrates, but these were sufficiently advanced for the conjunctive tissue to have evolved up to a perfectly osseous state.—On the presence of the Lower Devonian in the Western Sahara, by M. G. B. M. Flamand.—On the seismic movements and magnetic disturbances at the commencement of May at the station of Uccle, Belgium, by M. Eug. Lagrange.—On the ashes from the eruptions of Mont Pelée in 1851 and 1902, by M. A. Lacroix. The products of the present eruption are different from those thrown out in 1851.—On vaccination against plague, cholera and typhoid, by M. Besredka.

DIARY OF SOCIETIES.

THURSDAY, JUNE 12.

ROYAL SOCIETY, at 4.30.—(1) The Influence of an Atmosphere of Oxygen on the Respiratory Exchange. (2) The Influence of High Pressure of Oxygen on the Circulation of the Blood: L. Hill, F.R.S., and J. J. R. Macleod.—On the Parasitism of *Pseudomonas destructans* (Potter): Prof. M. C. Potter.—On the Toxic Properties of the Saliva of certain "Non-Poisonous" Colubrines: Prof. A. Alcock, F.R.S., and Dr. L. Rogers.—The Dissipation of Energy by Electric Currents induced in an Iron Cylinder when Rotated in a Magnetic Field: Prof. E. Wilson.

FRIDAY, JUNE 13.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Observations of Jupiter made at Mr. Crossley's Observatory, 1901: J. Gledhill.—Further Observations of Nova Persei: A. Stanley Williams.—A Dark Reticle: C. S. Howe.—Ephemeris for Physical Observations of Mars, 1902–3: A. C. D. Crommelin.—On the Distribution of the Stars in the Cape Photographic Durchmusterung: A. M. W. Downing.—Reductions of Photographs of Swift's Comet (*a* 1899) taken at Cambridge Observatory with a Portrait Lens: L. N. G. Filon.—On the Principle of the Arithmetic Mean: H. C. Plummer.—Observations of the Total Eclipse of the Moon, 1902 April 22: Perth Observatory, Western Australia.—*Probable paper*:—Experimental Reduction of Photographs of Eros for the Determination of Solar Parallax, Second Paper: A. R. Hinks.

MONDAY, JUNE 16.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Geographical and Archæological Explorations in Chinese Turkestan: Dr. M. A. Stein.

TUESDAY, JUNE 17.

ZOOLOGICAL SOCIETY, at 8.30.—Certain Habits of Animals traced in the Arrangement of their Hair: Dr. Walter Kidd.—On the Carpal Organ in the Female *Hapalemur griseus*: F. E. Beddard, F.R.S.—On some Points in the Anatomy of the Alimentary and Nervous Systems of the Pedipalpi: R. I. Pocock.

On the Vapour Pressures of Liquid Oxygen at Temperatures below its Boiling Point, and the Constant Volume Hydrogen and Helium Scales: Dr. M. W. Travers, G. Senter and Dr. A. Jacquerod.—On the Measurement of Temperature. Part III. On the Vapour Pressures of Liquid Hydrogen at Temperatures below its Boiling Point on the Constant Volume Hydrogen and Helium Scales: Dr. M. W. Travers and Dr. A. Jacquerod.

LINNEAN SOCIETY, at 8.—On Obesiella, a New Genus of Copepoda: Dr. W. G. Ridewood.—On Modern Methods in Mycology: Mr. G. Massee.—Further Observations on the Owls, especially their Skeleton: W. P. Pycraft.

CONTENTS.

THURSDAY, JUNE 19, 1902.

THE PLACE OF LAMARCK IN THE HISTORY OF EVOLUTION.

Lamarck, the Founder of Evolution; his Life and Work. With Translations of his Writings on Organic Evolution. By Alpheus S. Packard, M.D., LL.D., Professor of Zoology and Geology in Brown University, &c. Pp. xiv + 451. (London and New York: Longmans, Green and Co., 1901.) Price 9s. net.

THE name of Lamarck has of late been much in people's mouths. Now that the doctrine of organic evolution has secured acceptance from all those who are qualified to form an opinion on the subject, an attempt is being made in some quarters to deprive Darwin, the real hero of the campaign, of at least a portion of his laurels, and to bestow them on a leader of inferior rank and far lower achievement. It cannot be doubted that this attempt is, in the long run, doomed to failure; but in the meantime there is considerable danger of an unwholesome reaction among those who have not perfectly comprehended the points at issue.

It is often forgotten that the idea of "special creation," or, as we should rather say, of the "immutability of species," is one of comparatively recent growth. Before the seventeenth century the current notions on this subject were by no means rigid, while the terms "genus" and "species," in their technical use, were the exclusive property of logicians. It is not until the time of Ray that we find the latter term borrowed by a naturalist in order to give precision to a conception which was then a novelty to the scientific mind. The definition of natural species in the Linnæan sense would have sounded as strange in the ears of Francis Bacon as would the denial of spontaneous generation. The work of Ray, Linnæus and Cuvier, greatly as it assisted the cause of science, carried with it a fatal defect. It left order where it had found confusion, but in substituting exactness of definition for the vague conceptions of a former age, it did much to obscure the rudimentary notions of organic evolution which had influenced naturalists and philosophers from Aristotle downwards.

Nevertheless, the old transformist beliefs, though no longer popular, were not left quite without a witness. Buffon, being possibly influenced by considerations other than scientific, vacillated, as is well known, between the theories of mutability and fixity of species. Erasmus Darwin, on the other hand, was a vigorous and outspoken upholder of the transformist opinion, shorn of some, but not all, of its former crudities. Geoffroy St. Hilaire declared in favour of the derivation of different species from the same type; and six years later Lamarck, who had previously taught the fixity of species, announced his adherence to the evolutionary view. The author of the "Vestiges of Creation" and Herbert Spencer may be said in some sort to have carried on the transformist succession, but it was reserved for Charles Darwin and Alfred Russel Wallace to import into the problem an entirely fresh set of considerations, and by means of a new and illuminating theory, supported on a secure basis of fact, to win universal acceptance for a doctrine which all the skill and eloquence of its former advocates had failed to commend to the scientific world.

Prof. Packard, on the title-page of the present work, calls Lamarck "the founder of evolution." If the foregoing may be taken as a not unfair presentment of the course of opinion on the subject of transformism, it is difficult to see how such a claim can be justified. It is idle to discuss whether or not Lamarck was acquainted with the works of Erasmus Darwin. Transformism was in the air, and it is impossible to credit Lamarck with the origination of a view which had been present to the minds of Geoffroy St. Hilaire and of Buffon. Neither can it be said that Lamarck's advocacy won general approval for a doctrine that was previously discredited. The strength of his own convictions and the persistence with which he urged them are not in question; but the fact that he failed to convert either his contemporaries or his successors is equally indisputable. The only ground on which, if on any, the claim advanced on behalf of Lamarck can be sustained is the allegation that he was the first to render the doctrine of transmutation credible by pointing out the methods on which organic evolution has proceeded. Much, no doubt, depends on the acceptance or rejection of the so-called "Lamarckian factors." In the earlier stages of the present phase of the evolutionary controversy, these factors were somewhat uncritically accepted as adjuvants to the theory of natural selection propounded by Darwin and Wallace. But when the belief in the inheritance of acquired characters had once been seriously called in question, it was speedily perceived that no logical necessity existed for evolutionists to accept these factors at all. The question became clearly one of evidence; and in the opinion of many, if not most, of the leaders of scientific thought, the upholders of the Lamarckian view have so far failed to deal successfully with the burden of proof that undoubtedly rests upon them. The hereditary transmission of individually acquired characters is a necessary part of the Lamarckian system, and until this point is established to the satisfaction of scientific opinion, it is at least premature to hail Lamarck as in any sense the founder of organic evolution. And even should the proof be forthcoming, the facts would still remain that many of Lamarck's views had been already foreshadowed, that his system contains much speculation unsupported by adequate evidence, and much that is demonstrably erroneous; moreover, that it failed in any appreciable degree to influence his contemporaries.

It is hardly necessary to point out how complete a contrast to this is afforded by the history of Darwinism. Founded on a basis of observation and experiment to which the Lamarckian speculations can lay no claim, and calling in the aid of a principle—that of natural selection—which, given the observed facts of variation, actually showed how the adaptation everywhere manifest in nature might have been brought about, the Darwinian system supplied an element of rationality which had hitherto been absent, and compelled the attention of those to whom the unsupported hypotheses of previous transformists had failed to appeal. The importance of Darwin's work is seen in its results. Under the influence of the "Origin of Species," Huxley, Lyell, Hooker and Asa Gray ranged themselves on the side of evolution;

the whole of the scientific world, with few exceptions, followed their example, and before his death Darwin had the satisfaction of knowing that the doctrine of evolution had become almost a commonplace in the minds of the reflecting and cultivated portion of the community.

Lamarck was unquestionably a capable, industrious and enthusiastic naturalist. He possesses the merit of having grasped the truth of organic evolution, though his views as to its methods were crude and his arguments in its favour unsubstantial. He also carried out the principle on a far larger scale and with greater amplification of detail than did any of his transformist predecessors, and to him we owe the first attempt at the construction of a scheme of phylogeny. But while we readily allow all this, it seems to us, for the reasons above given, that in the present work the importance of Lamarck and of his contribution to the progress of evolutionary theory is greatly over-estimated. Nevertheless, in putting before us within reasonable compass a careful and critical account of the little that is known of the life and circumstances of Lamarck, and of his relations with the leaders of scientific thought in France during a period which is full of interest, Dr. Packard has done real service. He seems inclined to complain that writers on evolution "do not know their Lamarck." Whether this be true or not, the extracts from Lamarck's writings here given are so representative and so copious that there will in future be no excuse for ignorance as to what Lamarck's tenets really were. It may be doubted whether the well-known chapters in Lyell's "Principles" do not really contain all that is requisite for forming a working estimate of the Lamarckian doctrine. But there are some to whom, for various reasons, a more extended acquaintance with this doctrine will be necessary, and who yet possess neither the time nor the opportunity for attacking the works of Lamarck in their original form. To such readers, if they are willing to show indulgence towards a certain amount of needless repetition and some occasional inaccuracy in translation and other matters, Dr. Packard's interesting and thorough-going volume may be recommended with confidence. ELEMENTARY CHEMISTRY.

Elementary Inorganic Chemistry. By James Walker, D.Sc., Ph.D., F.R.S. Pp. 265. (London: George Bell and Sons, 1901.) Price 3*s.* 6*d.*

Experimental Chemistry. By Lyman C. Newell, Ph.D., State Normal School, Lowell, Mass. Pp. xv + 410. (London: D. C. Heath and Co., 1902.) Price 5*s.*

Elementary Experimental Chemistry. By W. F. Watson, A.M., Furman University, South Carolina. Pp. 320. (New York: A. S. Barnes and Co., 1901.) Price 7*s.* net.

THE first of these books may be said to meet a distinct want, felt in this case by others than the author, and to meet it extremely well. It is an elementary treatise on chemistry imbued with the spirit of the times, but written with restraint and marked by the lucid and philosophic style characteristic of the best class of scientific writing. It is not an ancient garment embroidered with new ions, nor is it an aggravated *bouleversement* of the chemistry that was presented to us twenty years ago. It would probably do most chemists good to read it, and it is admirably adapted as a first college book for students. It contains the essentials of chemical theory and a really judicious selection of chemical facts, and it is to be commended, perhaps, most of all to examiners, whose sins in asking for unimportant facts abate but slowly. It is no book for those who have to charge their memories with Dutch liquid, puce-coloured oxide of lead and powder of Algaroth; yet it does not relegate the conception of mass action and reversible changes to a period of grave and senior study. It is, in fact, a book which can be unreservedly recommended, and Prof. Walker deserves our thanks for having written it.

Dr. Newell's book is a thoughtful and interesting attempt to improve upon the older kind of text-book, and the author endeavours to interweave a laboratory course with adequate descriptive matter. It is difficult to judge such a book fairly without putting it to practical use, but there seems every prospect that by using it as the author intends it to be used the student would be brought to the right view of chemical science and to a sound knowledge of the leading principles and facts. The book abounds in practical and theoretical problems, and encouragement is given to the discussion of laboratory results in class—a most valuable form of teaching. There is a tendency in books of this kind for some of the statements, questions and injunctions to become a little puerile, and to conjure up a picture of ingenuousness which, in the present writer's experience, is not often found in real life, at least among male students. However, there is not very much to complain of in this way. The book has obvious merits, and the author may fairly claim that it deserves a trial.

The third work under review is intended especially for students who only take one short course of chemistry. A reviewer will, according to his disposition, be either intimidated or exasperated by the author's statement that he is "profoundly grateful to ten different educators for reading the proof sheets and making valuable suggestions." To make any objections after this announcement seems perhaps rash; but at whatever cost, the author and the ten educators must be faced with the statement that to an eleventh educator the book has proved disappointing. The introduction to the work comprises ten pages, and it consists of a series of statements defining matter, chemical compounds and mechanical mixtures, atoms, molecules, indestructibility of matter and conservation of energy. It is difficult to know what purpose is served by confronting the student at the very outset of chemical study with a series of dogmas such as are found here. The idea of the atom, for instance, is introduced by the statement that "a single symbol as C and Cl indicates *one atom* of the element." Immediately upon this comes "An atom is the smallest portion of matter that can take part in a chemical change. It is indivisible."

The atom being thus disposed of, the molecule is dealt with in like fashion. It is really astonishing to find this kind of thing in a book with such pretensions as are set forth in the preface. The rest of the book is of the same mould; there is nothing to distinguish it from dozens of other elementary chemical books of the kind that in this country have had their day and are happily

ceasing to be. A careful perusal has disclosed nothing that can give a well-intentioned critic occasion to say "this is a happy idea—that is capitally put—this is something to help us." On the contrary, if this book were to be reviewed in detail, it would be necessary to write columns of complaint. One feature of novelty appears in the book in the form of full-page illustrations of apparatus and materials used in all the experiments. These pictures are reproduced from photographs, and show three tiers of apparatus arranged as if for sale. In many cases it is not easy for an experienced chemist to recognise the individual pieces, and in plate xx. we reach a climax. It represents on the top shelf two tin canisters, a stoppered bottle, a Bunsen burner, a beaker, a tin dish, a blowpipe and another stoppered bottle. On the next shelf are three stoppered bottles, a hammer, four tin canisters, a small structure like a dog kennel, and a rack of twelve test-tubes. On the bottom shelf are two developing trays, a beaker, a stoppered bottle, a sugar basin, a stone gingerbeer bottle, a pocket handkerchief and apparently a bank-note or a shirt cuff. The plate bears the legend "The Metals." By the use of a lens one word of two of the labels can be deciphered.

A. S.

SOLID GEOMETRY.

The Elements of Euclid, Book XI. By R. Lachlan, Sc.D. Pp. 51. (London: Edward Arnold, n.d.) Price 1*s*.

IT is to be hoped that some of the scientific committees which are now dealing with the improvement of mathematical teaching, and more especially with that of the teaching of elementary geometry, will, in the process of pruning Euclid, direct attention to this little-read Book xi. As in other books of the Elements, many of the propositions are of the trivial, or even ludicrous, character, while some of the definitions lack precision. For example, can prop. 1—"one part of a straight line cannot lie in a plane and another part without the plane"—be seriously regarded as necessary? Indeed, the proof assumes the thing which it seeks to prove: let A B C be the given straight line; let a part of it, A B, lie in the plane, and a part, B C (if possible), out of the plane; produce A B *in the plane* to any point, D, &c. To this several other instances might be added.

Then as regards definition, the descriptions of dihedral, trihedral and (generally) polyhedral angles leave something to be desired. Possibly some better term than *angle* can be found in such cases. We are told that "when two planes meet and are terminated at their line of intersection, they are said to form a dihedral angle"; "when several planes meet in a point, they are said to form a polyhedral angle." All that such planes visibly "form" is a certain figure; the "angle" which they form (as it is employed in subsequent mathematics) is, in reality, an *area* on a sphere of unit radius. It is true that Book xi. is not concerned with this precise quantitative definition of (so-called) *solid angles*—better called *conical angles*—but merely with certain plane, or face, angles connected with them; nevertheless, it may be desirable to give the student, who when he reaches Book xi. can scarcely be called a *beginner*, this quantitative notion.

In the small compass of this book there is little opportunity for anything strikingly original or novel. Dr. Lachlan finishes it with an appendix which contains a large number of propositions, examples, &c., and this appendix will be found much more valuable than Book xi. itself.

A few criticisms of a minor character may not be out of place. We notice that in the enunciation of each proposition, Dr. Lachlan always uses the simple word "is" or "are" when the proposition states a fact which can be proved; thus, "if two planes intersect, their line of intersection is a straight line." The typical editor of a modern Euclid would say "their line of intersection *shall be* a straight line," employing a ridiculous compulsory form of expression. There is now the beginning of a revulsion against this style, which has been considered for some curious reason to be appropriate and essential to Euclid, but to no other subject of study or conversation. So far, Dr. Lachlan is in agreement with common sense; but why does he, when setting out on the proof of the proposition, re-state the fact with a "shall be"? Twice he forgot his rule—in prop. 1, where "must be" is employed, and prop. 14, where the simple and sensible "are" of the formal enunciation remains "are" in the re-statement.

The proof of prop. 20 would avoid a tendency to mislead the student if it stated that the point C is first taken (arbitrarily), then E, and finally B and D by drawing *any* line, E B D, through E.

In the third line of the proof of prop. 21, the proof is rendered very much more clear by the insertion of the word "all" before the words "the $\angle$s," the statement then being the very obvious one that if there are two sets of fifty plane triangles, the sum of all the angles in the first set is equal to the sum of all those in the second set.

Finally, the employment of the word "power" in the definition (p. 536) "the square on the distance between a point and the centre of a sphere less the square on the radius of the sphere is called the power of the point with respect to the sphere" does not seem justifiable or necessary, although it has been employed by a geometer of high repute. The word *power* is already employed in science for something quite different from the square of a tangent. Indeed, a student of electricity might be tempted to think that this geometrical "power of points" is a mere pun on the well-known term used in connection with frictional machines. Everything must not be sacrificed to brevity; if new terms are wanted in science, they should be appropriate and expressive.

BELGIAN BOTANICAL INVESTIGATIONS.

Recueil de l'Institut Botanique (Université de Bruxelles). Par L. Errera. Tome v. Pp. xii + 357. (Bruxelles: Henri Lamertin, 1902.)

IN this book there are brought together recent papers by botanists of the Royal Academy of Belgium, which have already been published in different journals during the last two years. Although this is the first volume to be published, it appears as vol. v., since the first four volumes will be given up to earlier papers. Thus

the five volumes will provide a systematic record of various lines of research, mainly physiological, which have been the subjects of investigation in the Botanical Institute of Brussels.

The nature of the alkaloids found in plants and the methods of localising them is one of these subjects, and in the present volume there are two papers dealing with those bodies, the one by the late M. George Clautriau, on "The Nature and Significance of Alkaloids in Plants," the other by E. Vanderlinden, treating of alkaloids in the Ranunculaceæ. A considerable part of Clautriau's paper is historical, the present research being confined to caffeine obtained from coffee and tea plants. Having previously studied the alkaloids in various other plants, he is well qualified to summarise our present knowledge of them. Although alkaloids have only been located in a limited number of plants, Clautriau considers that they are probably formed in all plants, but not always in sufficient quantity to be stored up. Alkaloids derived from purine bases are found throughout the whole range of plants, while those derived from a pyridine base are confined almost exclusively to Angiosperms. Definite microchemical tests for alkaloids are wanting; thus Clautriau was unable to obtain any which would enable him to detect caffeine *in situ*. He concludes that alkaloids are decomposition products formed in the breaking down of proteids; that they can be worked up again, but this requires a considerable expenditure of energy, and that generally their function is to protect the plant. Vanderlinden's results are quite in harmony with Clautriau's views. He finds that the amount of alkaloid present in a plant is liable to fluctuations, these depending upon the phase of vegetation and the nature of the soil. Curiously, Ranunculus and Clematis, two genera well known to possess toxic properties, yield no alkaloid.

In a second paper, Clautriau describes his experiments on pitcher-plants, some of which were performed on plants in their natural habitat in Java, others after his return to Brussels. Vines, who has reinvestigated the subject on the strength of Clautriau's results, does not confirm them, but decides that the ferment is tryptic, not peptic.

In the course of his experiments on the permeability of protoplasm to liquids at different temperatures, van Rysselburgh disproves the view held by Schwendener and others that protoplasm is not permeable to water at 0° C.; in fact, he finds that it is permeable to potassium nitrate, urea, methylene-blue, &c., at the same temperature. Another important observation was made that the sap in a cell if isotonic with a certain solution at any temperature will be isotonic with it for all temperatures.

M. Jean Massart advances some decidedly unconventional ideas on the phylogeny of the lower organisms, which presumably have originated during his investigation of the protoplasm of the Schizophyta. His deductions as to the nature of the central body in the Schizophyceæ and the stainable bodies in Bacteria are somewhat convincing, but at present many problems of the nucleus seem to be beyond our powers of solution. The last few pages of the publication are devoted to the description of a gigantic Bacterium, *Spirillum colossus*, obtained by Prof. Errera from an ancient moat.

OUR BOOK SHELF.

Dynamos, Alternators and Transformers. By Gisbert Kapp. Translated from the third German edition by H. H. Simmons, A.M.I.E.E. Pp. v + 503. (London: Biggs and Co.) Price 10*s.* 6*d.*

Étude Pratique sur les Différents Systèmes d'Éclairage. By J. Defays and H. Pittet. Pp. 168. (Paris: Gauthier-Villars, n.d.) Price fr. 3.

MR. KAPP'S book has passed through a somewhat curious development. Originally written in English, it first appeared in German as a translation; subsequently Mr. Kapp revised, and to a large extent re-wrote, the German translation, the revised book appearing as the third German edition in 1899. It is this work which has now been translated by Mr. Simmons. The general merits of the book are probably known to most electrical engineers; those who are only familiar with the earlier English edition will find much that is new and valuable in the one now before us. After some opening chapters on the electric and magnetic theory underlying the design of dynamos, the winding of armatures is considered in detail in a couple of chapters well illustrated by diagrams. The next chapter deals with field magnets, after which armature reaction, commutation and sparkless collection are considered at some length. Some typical examples of direct-current machines are described, but at no great length, as this ground has already been covered by Mr. Kapp in his "Dynamo Construction: Electrical and Mechanical." The remainder of the book deals in a similar manner with alternators, synchronous and asynchronous motors, and rotary converters. Graphical methods are employed in this part to a considerable extent; the mathematical treatment throughout the book is clear and concise, a certain familiarity with the differential and integral calculus being assumed in the reader. As a whole the work forms a most valuable text-book for the student of this branch of electrical engineering.

It will be noticed that the book does not deal at all with transformers; this is because a separate work on this subject has been published by the author, a fact which is stated in the preface. Yet in spite of this, the title as it appears on the cover and page headings is "Dynamos, Alternators and Transformers," which is, to say the least, misleading. On the title-page a different, and more accurate, name is given to the book. This defect is to be regretted, as it mars an otherwise excellent work.

MM. Defays and Pittet's volume cannot fail to prove attractive to those who are interested in the problems of artificial lighting. The authors have aimed at providing a practical guide to those who are called upon to select, as, for example, for lighting a factory, a suitable system of illumination. Naturally, in such a case, the question of relative cost is of prime importance; the authors have, however, rightly abstained from dwelling too strongly on this point, as not only is the price so largely a question of locality, but it is often very difficult, if not impossible, to decide what is the monetary equivalent of the advantages which one illuminant possesses over another. The whole subject of artificial illumination is first dealt with in a general manner, the considerations of importance in relation to different conditions of use being pointed out. After this, separate chapters are devoted to a detailed examination of lighting by gas, acetylene, oil, alcohol and electricity. The principles underlying each system are expounded clearly and not too technically, and its security, healthiness and efficiency are discussed. From the hygienic point of view there can be no question as to the superiority of electric light; it is also more convenient, and probably safer, than any other method; but unfortunately it is considerably dearer, unless regarded from the enlightened standpoint which takes into account

the value of health and convenience. Second in healthiness, probably, comes incandescent gas lighting, and this is also the cheapest. For comparative figures we must refer readers to the book itself, in which many useful and interesting tables are given. The book would be improved by the addition of illustrations, which are more especially needed to accompany the descriptions of different forms of gas burners and lamps. We also think that it would be advantageous if the very short chapter on the distribution of light, and the use of shades, &c., were expanded, as this is a subject on which the public more especially needs instruction, since it is that which, more than any other, they have under their own control. M. S.

Sanitary Engineering. A Practical Manual of Town Drainage and Sewage and Refuse Disposal. By Francis Wood, A.M. Inst. C.E., F.G.S. With numerous illustrations. Pp. xi + 304. (London: Charles Griffin and Co., Ltd., 1902.) Price 8*s*. 6*d*. net.

SANITARY engineering is a comprehensive and difficult science, yet the author states in his preface that he himself "felt the want of a work which would in one small volume deal with the science in a comprehensive, concise and easily intelligible form." It is fair to infer from this statement that he considers the want has been met by the compilation of the present work. Yet in his introductory remarks (chapter i.) he adds that the student "will know only a small part of this vast subject when he has read and learned the contents of the present volume." We concur with the writer in the latter statement. The work contains a great deal of information upon sanitary engineering which will be useful to municipal engineers and students, medical officers of health, sanitary inspectors and members of local authorities; but the subject is of course not dealt with comprehensively. The general correctness of the statements and views expressed leave little to be desired, but while in a scientific text-book there is no occasion to be hypercritical on the subject of literary style, there are so many instances in this work where the meaning is obscured or the sense is lost by the slovenly construction of sentences that the pleasure and satisfaction of perusing it are somewhat marred. To give one or two instances:—

"The student must therefore take and make the most of the opportunities which he now has—and never will have again" (p. 5).

"The engineer is a born geologist; his work is connected with the earth and its composition" (p. 5).

"Since the system of bacteriology has been brought forward" (p. 227).

"The formation of Urban, Rural District, and Parish Councils are doing a great work in abolishing these abominations; and it is pleasing to note that in almost every district and village sanitary inspectors are being appointed, who with the powers they possess are rapidly converting these anomalies, which soon must become things of the past" (p. 49).

The author is inclined to conclude that the explanation why sewer air may at times be quite sweet is "that micro-organisms also act on the foul atmosphere and consume each other, together with the foul matter in the gases which must prevade it" (p. 124).

We read with some curiosity and misgivings the statement that a chapter had been allotted to bacteriolysis —but, as we suspected, the chapter deals with the bacteriological purification of sewage. On pp. 170–180, an article which appeared in *The Engineer* about four years ago is inserted, and the writer advises that "the paragraphs under their different headings should be read in conjunction with the same subjects, which are to be found elsewhere" in the book. One need hardly point out that this is not the most convenient way in which the subject-matter can be presented to the student. The author would have done well if he had himself selected the different paragraphs contained in the article and put them under their proper headings. The work, however, in addition to containing much valuable information, is very well illustrated, and the subject-matter dealt with comprises a fairly wide survey of the more important matters of practical sanitary engineering.

The Story of Animal Life. By B. Lindsay. The Library of Useful Stories. Pp. viii + 208. (London: George Newnes, Ltd., 1901.) Price 1*s*.

TO try to tell the story of animal life within the compass of one of Messrs. Newnes' well-known shilling series of "Useful Stories" seems almost irreverent. Even Prof. Macalister required two primers, and the result was somewhat indigestible pemmican. Perhaps Huxley's educational genius might have achieved what must seem to most naturalists impossible. We therefore admire Miss Lindsay's courage, and while we think that she has attempted too much, we willingly recognise that her little book is good value for a shilling—a *multum in parvo*, packed with interesting information and illumined with big ideas. It is perhaps unduly handicapped with technicalities and zoological subtleties, for when we read of "diploblastic," "apopyles," "metamerism," "Archiannelida," "Euthyneura," "Adelochorda," and so on, we wonder what these abstruse terms are doing in this shilling gallery. On the other hand, the booklet is interesting, and it has the two-fold merit of refusing to give a false simplicity to the subject, and of clearly indicating that zoology is not remote from human life. We regret to notice some inaccuracies of spelling and grammar which might have been readily avoided in so small a book. We regret still more to have to point out that many of the figures are so roughly reproduced that they recall the earliest stages of book illustration. Some of them, *e.g.* the tadpoles, are worse than mediæval, and if they were not so dull might be referred to as beacons warning us of the dangers of cheapness.

Municipal Engineering and Sanitation. By M. M. Baker, Ph.D., C.E. Pp. viii + 317. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1902.) Price 5*s*. net.

THE author intends this small volume for that large and rapidly growing class of persons who, either as officials or citizens, are striving to improve municipal conditions. It is a short review of the whole field of engineering and municipal sanitation, and no claim is made that it is an exhaustive study of any one of the branches with which it deals.

Although engineers and sanitarians will not find in the book much that is new to them, yet it contains matter of a trustworthy and up-to-date nature which will make the book interesting and helpful even to professional men. In addition to the treatment of the subjects of water-supply, sewage and sewerage, general scavenging and the making and keeping of streets and pavements, the following matters are also dealt with:—subways for pipes and wires; urban and inter-urban transportation; bridges, ferries and ice boats; docks and harbour facilities; telegraph, telephone and messenger service; ice; milk; markets; slaughter-houses; lighting; cemeteries; crematoria; fire; smoke; noises; disinfection; parks; playgrounds; baths and lavatories; public offices; and the administration, finance and public policy of municipal authorities.

Having regard to the extensive range of subjects dealt with, it follows that in such a small volume the treatment of each subject must be, generally speaking, sketchy. For instance, the chapter upon disinfecting methods and apparatus consists of three small pages containing some 750 words only. The book is of a handy size, well printed and bound, but without illustrations.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Astronomy in the University of London.

IT seems desirable to call special attention to the change which has recently been made in the conditions with regard to astronomy for the B.Sc. Pass and Honours degrees of the University of London. This is the more important as, owing to an unfortunate slip of the much-overworked academic Registrar, the point was omitted from the published examination schedules, and has only been corrected by an attached slip in recent issues.

The point is this, that in future astronomy is to be counted as an independent subject for the B.Sc. degree. It will rank equally with geology, botany or zoology. It is true that the Faculty of Arts has retained a certain amount of astronomy in its mathematical syllabus—in my opinion a very poor syllabus—which represents, not modern astronomy, but the condition of affairs in "three day papers" at Cambridge fifty years ago, when the University of London was founded. Why the Faculty of Arts does not insist also on a little antiquated geology and a little pre-Darwinian biology is cause for wonder. At any rate, the Faculty of Science has recognised that astronomy is a suitable subject for graduation, and we may hope that students of astronomical physics and theoretical and observational astronomy will realise that they can now specialise in London before graduating. A Pass student will be able to graduate by studying mathematics, physics and astronomy, and an Honours student by taking astronomy and *either* mathematics *or* physics. We may hope that a school of astronomy will form itself in London free from the traditions of the Cambridge Mathematical Tripos, and recognising mathematics for the astronomer as ancillary only to observational and physical work. KARL PEARSON.

University College, London, June 15.

De Vriesian Species.

THE recent work of Prof. H. de Vries on the origin of species by mutation has attracted a great deal of attention, although it cannot be said that the facts he presents are of a new kind, or that, taken by themselves, they prove anything about the origin of species. The great merit of the work is to be found in its clear presentation of the subject, with carefully worked out examples, at an opportune time. In former years botanists were not so ready as they are to-day to recognise apparently minor characters as specific, and the great variety of slightly modified plant forms passed almost unnoticed. It was not considered worth while to investigate the polymorphism of the old specific aggregates, and men like Jordan, who did so, were not regarded altogether favourably. The old conception of species seemed to give us a superabundance of plant types, taking the world over; and many botanists thought, as one recently said to me, that it was impossible to catalogue and name the minor forms, *because they were infinitely numerous.* However, there has arisen a new school, especially dominant in America, which recognises the fact that many of the old specific names cover a number of types which are readily distinguishable from one another. These may intergrade, but in many cases they do not seem to do so, and though the distinctions may seem small, they are perfectly constant. The result of the new investigations is in many cases to increase the number of recognised species four-fold, ten-fold, or more. Now when one comes to study these numerous species, it is evident that much of the difference is not absolute, but consists in different combinations of the same or similar characters, like the patterns of a kaleidoscope. With a little ingenuity, one could almost predict the characters of undiscovered forms. Heredity seems every now and then to take a new throw of the dice, with results exactly such as de Vries has described. The successful throws are those which give results adapted to the environment, and these, under the laws governing the survival of the fittest, give us what we proceed to describe as new species.

The proof that species do thus originate is not to be found in garden experiments alone, but must be confirmed by field observations. Unfortunately, the average systematic botanist seems to be much more interested in defending his "new species" than in asking whether they may not be "new" in a more literal sense than he imagines. Nevertheless, search will be made for "de Vriesian species," and thereby the true status of many described plants may be revealed. Two instances of such which have lately come to my notice may be worth recording.

(1) *Helianthus petiolaris phenax* (new variety). Rays 13, mustard yellow, 11 mm. diameter; corollas and stigmas yellow, giving the flower a yellow disc. Found at Boulder, Colorado, August, 1901, growing in a field full of normal *H. petiolaris*, with deep saffron-yellow rays about 8 mm. diameter, and corolla and stigmas a very dark wine red. I took both plants to the meeting of the American Association for the Advancement of Science at Denver, and showed them to an eminent botanist who knows the flora of Colorado well, and is not regarded as a "splitter." I said, "these appear to be forms of one species." "Oh, no," he replied, "one is a Helianthus, the other a Rudbeckia!" However, the flowers were carefully examined in company with Prof. Pammel, and were also shown to Miss Eastwood, and no doubt remained that the new variety was really an offshoot from *H. petiolaris*, which had probably originated where it was found. The variation is the more interesting because in the sunflowers (Helianthus) the colour of the disc is used as a character to separate groups of species.

(2) *Ribes cereum viridior* (new variety). Plant perhaps more resinous; tube of calyx shorter, pale greenish, stigma exserted beyond petals. Fruit deep red, small, perfectly spherical. Found (first by my wife) between San Ignacio and Las Vegas, New Mexico. A clump of bushes presenting these characters (observed in two seasons) grows only a few yards away from plenty of what Mr. Coville considers genuine *R. cereum*, with a longer calyx-tube, streaked with purplish pink, and fruit a little larger and more inclined to be oblong. I was at first quite sure I had a valid species in this *viridior* variety, and Mr. Coville, before we got the fruit, thought the specimens might be his *R. mescalerium*, which has black fruit. Now, however, it appears reasonably certain that the plant represents a de Vriesian "species" or mutation. Miss Eastwood has lately described a somewhat similar mutation of a Californian species, under the name *Ribes sericeum viridescens*. T. D. A. COCKERELL.

East Las Vegas, New Mexico, U.S.A., May 22.

Formula for the Perimeter of an Ellipse.

THE formula given by your Queensland correspondent (NATURE of April 10, p. 536) for the perimeter of an ellipse is not at all objectionable on the score of degree of approximation. It leads, however, to another, which for practical purposes is much preferable. If for shortness' sake λ be written for $\log 2/\log \frac{1}{2}\pi$, he says in effect that the perimeter of an ellipse with semi-axes a and b is approximately equal to the circumference of a circle of radius

$$\left(\frac{a^\lambda + b^\lambda}{2}\right)^{\frac{1}{\lambda}}.$$

Now $\lambda = \cdot 3010300/\cdot 1961199$, two convergents to which are $3/2$ and $20/13$. Taking the former of these—a course which entails the extraction of no roots other than the square and the cube—we obtain the following result:—The perimeter of an ellipse is approximately equal to the circumference of a circle the radius of which is the semi-cubic mean of the semi-axes of the ellipse (see *Messenger of Math.*, xii. pp. 149–151; *Proc.* Manchester Lit. and Phil. Soc., February 1, 1901).

But by far the best result of this kind known to me may be put in the shape of a rule as follows:—To obtain the radius of a circle the circumference of which will be a close approximation to the perimeter of a given ellipse, diminish twenty-one times the arithmetic mean of the semi-axes of the ellipse by twice the geometric mean and thrice the harmonic mean and divide the remainder by 16. As an illustration of the value of this, we may take the classical example where $a = 1$ and $b = \cdot 8$. The three means A, G, H, referred to in the rule are then $\cdot 9$, $\sqrt{\cdot 8}$, $8/9$ and

$$\begin{aligned}\frac{21A - 2G - 3H}{16} &= \frac{18\cdot 9 - \frac{4}{5}\sqrt{5} - 2\frac{2}{3}}{16}, \\ &= \frac{18\cdot 9 - (1\cdot 7888544 - 2\cdot 6666666)}{16}, \\ &= \frac{18\cdot 9 - 4\cdot 4555210}{16}, \\ &= \frac{14\cdot 4444790}{16}, \\ &= \cdot 90277993\ldots\end{aligned}$$

Now, according to Legendre, the perimeter in this case is $2\pi(\cdot 90277992)$, so that the rule gives the desired result correct to within one hundred-millionth of 2π. THOMAS MUIR.

Cape Town, South Africa, May 19.

The "Armorl" Electro-Capillary Relay.

IN reply to your correspondent "J.-S." (p. 151), I may say that the model which I saw did actually work; it illustrated the flow of mercury from a fine jet when subjected to the influence of a small electromotive force, in the same way as described with reference to Fig. 1 of my article. I think your correspondent slightly misunderstands the principle of the instrument; it is not the small movement of the mercury, such as is used in the ordinary capillary electrometer, which works the relay lever; this movement merely serves to force some of the mercury out of the jet, and the *falling mercury* then moves the lever.

The inventors claimed that they had succeeded in effecting so nice a balance of forces that the mercury flowed from the jet under a very small influence. I join with your correspondent in the desire (which I expressed also in my article) that some trustworthy data concerning the instrument should be published.

June 13. THE WRITER OF THE ARTICLE.

SCIENCE AND MILITARY EDUCATION.

THE report of the Military Education Committee was issued to the public on Saturday, June 7, and has been the subject of much comment in the Press. The conclusions and recommendations of the Committee have been well-received on the whole, though there are some exceptions, as in the case of the *Spectator*, which would wish to see Sandhurst done away with, or rather used in an entirely different manner and at a later stage in the officer's career, and in that of the military correspondent of the *Times*, who, in the course of a long article, falls foul of an important passage relating to science, and in effect advises the War Office not to accept or act upon the recommendations of the Committee on this subject. The writer of the article goes so far, indeed, as to suggest that the Committee has not sufficiently considered the evidence, quoting Sir George Clarke in support of the merits of Latin in such a way that we were not a little surprised on turning to Sir George's evidence to find that, when questioned as to the proper preliminary training of cadets (Question 839), he expressed the opinion that they should have a "broad, liberal education," adding that "the broader it is and the wider its scope, and the sounder generally, the better it will fit them for the special training they receive afterwards."

The passage objected to by the *Times* correspondent (20) will be found on p. 5, and, appearing as it does over the signatures of two such eminent representatives of classical training as the head masters of Eton and St. Paul's, is so important that we print it in full. It is as follows:—

"The fifth subject which may be considered as an essential part of a sound general education is experimental science, that is to say, the science of physics and chemistry treated experimentally. As a means of mental training, and also viewed as useful knowledge, this may be considered a necessary part of the intellectual equipment of every educated man, and especially so of the officer, whose profession in all its branches is daily becoming more and more dependent on science."

Considering the uncompromising terms of this statement, it is disappointing to find that a committee holding such clear and strong views should have found itself, in the event, unable to agree upon a scheme which would ensure that this "necessary part of the intellectual equipment of every educated man" should be provided for each and all our future officers. For it cannot be denied that the actual position proposed for science in the scheme recommended, viz. that it should be alternative in Class I. with Latin, will put it in the power of opponents of science to prevent candidates who may come under their influence from having the opportunity of securing this "essential part of a sound general education."

In saying this we do not overlook the fact, as some are disposed to do, that the proposed arrangements will allow those who select Latin as their subject in Class I. to offer science as a Class II. subject, and that, consequently, neither of these two necessary subjects need be neglected. But after making all allowance for the manner in which the scheme as a whole will qualify the effect of the relations of Latin and science in Class I., we think the Committee has not sufficiently regarded the fact that as Latin is begun at a very early age, but chemistry and physics much later, candidates choosing their subjects at about fifteen, as many, and perhaps most, of them must do, will be much more likely to select the former than the latter from Class I. (see Questions 8630, 8631, 8632), leaving science for Group II., where, however, it becomes an alternative with several other subjects, and so is very likely to be squeezed out.

It is a striking illustration of the effects of the neglect of science in our educational system, which even now is being remedied but slowly in some of our schools, that so many soldiers and others still make the mistake of supposing that as regards science the Army only needs "a proportion of scientific experts among military officers for suggesting and following up improvements in *matériel*," and that "the majority of such experts can be better obtained from civilian sources outside the Army than from within its ranks." The last part of this statement is, indeed, in spite of all the fine qualities of our officers, only too sadly true. But it is just because the basis of military education (and indeed of nearly all English education in the case of the abler members of the higher classes) has been too narrow in the past that the Army has failed to throw up a sufficient supply, we will not say of trained scientific specialists, but of officers capable of understanding the specialists, of absorbing their ideas, mastering their methods and applying these in the operations of war. How can we expect average men whose training has been mainly in language and mathematics to be resourceful and confident when brought face to face with the problems created for their profession by the revolutions of the last half century? Every question, said Liebig, one of the creators of much that is strongest in modern Germany, put to science clearly and definitely has been satisfactorily answered before long. Only when the inquirer has no precise idea of the problem to be solved does he remain unsatisfied for long. It is just because the majority of our officers have not had the broadest training possible, that so many are unable to make use of the new powers that science holds out to them, and are still under the mistaken impression that the main use of science in education lies in the facts which it provides.

It is clear that even now many educators and soldiers have not grasped the real elements of this great problem, and that they still fail to see that the object with which science is now taught is, not to convey a few more facts or a few facts of a new kind, but to preserve those habits of mind and that fertility of resource which daily become more important in face of the problems of modern life, and which are not to be gained by a purely literary and mathematical training. All will agree that faculties which must especially be cultivated in our officers "are power of command, habits of leadership, and the ability to act decisively and correctly at the right time and place." But when it is contended, as it often is, that "study in a chemical laboratory does not make for this kind of fitness," it is forgotten that laboratory work properly done will certainly develop these qualities at least as well, and probably better, than any study in

which books only are concerned, and that we do not teach either science or Latin, mathematics or modern languages primarily to produce the habit of command, but because the habit of command and the ability to act with decision have a tenfold value in the man who is many-sided in his knowledge and experience and who, in the language of the street, "knows where he is" in many departments of human activity.

The object of a training in experimental science is not to stuff the mind with knowledge, as so many still seem to think, but to open and prepare it to receive and rightly apply knowledge in the after working years of life. Those persons are indeed ignorant who suppose that in a modern course of work, let us say, in physics, a boy's mind is "stuffed with knowledge" or that a course of work in electricity gives less play to the imagination than getting up vocabularies or irregular verbs. But we must not follow a bad example; these things also make for goodness in their degree.

As we have said above, the report of the Committee has, as regards its main features, been received with a chorus of approval, and little remains to be said about it. We think the proposal of an expert educational committee with advisory powers excellent. We are glad that whilst science and Latin are alternative subjects in Class I., the subject not taken as a Class I. subject can be taken as a Class II. subject. At the same time, we regret that Sir Michael Foster did not succeed in prevailing on his colleagues to embody in their final recommendations the admirable opinion which we quote at the beginning of this article.

If we may judge from the tenor of the discussion at the Conference of Science Masters last Christmas, we think the proposed changes in regard to practical work in chemistry will be widely welcomed. But if this reform is to work well, no attempt must be made to *add* the new scheme of practical work to the old requirements in qualitative analysis. The time which did not suffice for the latter alone cannot be sufficient for both together. We believe, too, that many teachers both of chemistry and physics would be most willing to see the scope of the syllabus in their special subject reduced a little, in order to secure that all candidates taking science should include in their work the "pass part" portions of both the chemical and physical divisions of science.

A HOLIDAY CRUISE TO ALASKA.[1]

THESE two handsome and magnificently illustrated volumes should be brought to the notice of every man of wealth as a lesson in the art of spending a holiday. He will learn therefrom how this may be done with permanent satisfaction to himself and permanent advantage to science.

In a pointedly brief and unassuming preface the patron of the expedition explains that, having planned a summer cruise through Alaskan waters for himself and his family, he found that the steamer which he had chartered would accommodate a larger party, and therefore resolved to seek "some guests who, while adding to the interest and pleasure of the expedition, would gather useful information and distribute it for the benefit of others."

By the advice of his physician he obtained the aid of Dr. C. Hart Merriam, chief of the Biological Survey of the U.S. Department of Agriculture, in carrying out this plan.

The outcome is succinctly stated in the introduction (pp. xxv–xxxi) by Dr. Merriam, who has most capably fulfilled his duties as general editor to the records of the cruise:—

"In the early spring of 1899 Mr. Edward H. Harriman of New York, in cooperation with the Washington Academy of Sciences but entirely at his own expense, organised an expedition to Alaska. He invited as his guests three artists and twenty-five men of science, representing various branches of research and including well known professors in universities on both sides of the continent, and leaders in several branches of Government scientific work. . . . The expedition sailed from Seattle May 30 . . . and was gone just two months."

The ship threaded the "inside passages" from Puget Sound to Juneau, Skagway and Sitka; thence along the open coast to Cook Inlet and the Alaska Peninsula, and past the Aleutian Islands into Bering Sea, up to the entrance to Bering Strait, touching at Eskimo settlements on both the Asiatic and American coasts, and then turning homeward. The voyage was not in itself in any way remarkable; the interest centres in the personnel and methods of the expedition.

As for the personnel—the following list will show that the selected scientific party was qualified to take advantage of every opportunity. Botany was represented by F. V. Coville and T. H. Kearney, jun., of the U.S. Department of Agriculture, and by Prof. B. E. Fernow, of Cornell, Dr. A. Saunders and Dr. W. Trelease; zoology in its various branches by Dr. W. R. Coe, of Yale, D. G. Elliot, of the Field Columbian Museum, Dr. A. K. Fisher and Dr. C. H. Merriam, of the U.S. Department of Agriculture, R. Ridgway, of the Washington National Museum, C. A. Keeler, of the San Francisco Museum, Prof. W. E. Ritter, of the University of California, Prof. T. Kincaid, of the University of Washington State, and Dr. G. B. Grinnell; geology and geography by Dr. W. H. Dall, G. K. Gilbert and H. Gannett, of the U.S. Geological Survey, and Prof. B. K. Emerson, of Amherst; mineralogy by Dr. C. Palache, of Harvard, and W. B. Devereux; meteorology by Prof. W. H. Brewer, of Yale; and nature-lore in its literary aspect by John Burroughs and John Muir. Of the three artists on the ship Mr. L. A. Fuertes was a specialist in bird-portraiture—sixteen of the many beautiful coloured plates which adorn these volumes attesting his skill. We learn, moreover, that a fourth artist was sent to Alaska in the following year for the special purpose of securing drawings and paintings of Alaskan plants! The expedition also included two photographers, two taxidermists, two stenographers; with a chaplain, two physicians and a trained nurse. The Harriman family party numbered eleven.

As for the methods—these seem to have been in every way admirable. Under unskilful management the scheme would probably have come to nought through the stress of divergent interests. But the patron of the expedition met the occasion like a whole-hearted democrat. His procedure is thus described by Dr. Merriam:—

"The day after leaving New York Mr. Harriman called together the members of the Expedition and announced that it was not his desire to dictate the route to be followed, or to control the details of the work. In accordance with his wishes a business organization was effected, comprising an executive committee, a committee on route and plans, and special committees on the various scientific activities. These committees, throughout the voyage, held frequent meetings and determined from day to day the operations of the expedition. . . .

"Among the unusual features which contributed to the success of the Expedition, three are worthy of special mention:—

"(1) The ship had no business other than to convey the party whithersoever it desired to go. Her route was entrusted to a committee comprising the heads of the various departments of research; so that from day to day and hour to hour her movements were made to subserve the interests of the scientific work.

"(2) The scientific staff represented varied interests and was made up of men trained in special lines of research.

[1] "Alaska. Harriman Alaska Expedition, 1899." 2 vols. Royal 8vo. Pp. xxxvii + 383, with 39 coloured plates, 85 photogravure plates, 240 text figures and 5 maps. Vol. i. Narrative, Glaciers, Natives. Vol. ii. History, Geography, Resources. By many authors. (New York: Doubleday, Page and Co., 1901.)

"(3) The equipment was comprehensive, including naphtha launches, small boats and canoes, camping outfits, stenographers, photographers, and extra men for oarsmen and helpers, thereby reducing to a minimum the time necessary to accomplish material results. . . ."

To indicate what *was* accomplished let us again quote Dr. Merriam :—

"During the two months' cruise a distance of nine thousand miles was traversed. Frequent landings were made, and, no matter how brief, were utilised by the artists, photographers, geologists, botanists, zoologists, and students of glaciers. From time to time longer stops were made and camping parties were put ashore that more thorough work might be done. Thus one or more camping parties operated at Glacier Bay, Yakutat Bay, Prince William Sound, Kadiak Island, the Alaska Peninsula and the Shumagin Islands. Large and important collections were made, including series of the small mammals and birds of the coast-region,"—

and here we may break off to note that Burroughs, in a later part of the volume (p. 62), mentions that one day the ship "made a voyage of sixty miles to enable our collectors to take up some traps, the total catch of which proved to be nine mice,"—

"enormous numbers of marine animals and seaweeds, and by far the largest collections of insects and land-plants ever brought from Alaska. There were also small collections of fossil shells and fossil plants. In working up this material the services of more than fifty specialists have been secured, and although the task is by no means finished, thirteen genera and nearly six hundred species new to science have already been discovered and described. The natural history specimens have not merely enriched our museums, they have increased many fold our knowledge of the fauna and flora of Alaska. . . .

"A number of glaciers not previously known, as well as many others which had been vaguely or imperfectly known, were mapped, photographed and described, and much evidence was gathered of changes that have occurred in their length and size. . . . In Prince William Sound a new fiord fifteen miles in length and abounding in glaciers was discovered, photographed, and mapped. . . . The large number of photographs taken by the professional photographers on board was materially increased by cameras belonging to various members of the Expedition, and in all not less than five thousand photographs were secured. These cover many parts of the coast region from British Columbia to Bering Strait, and constitute incomparably the best series of pictures of the region thus far obtained."

The publication of the results has been undertaken in the same well-ordered and liberal spirit. The two volumes before us

"contain the narrative of the expedition and a few papers on subjects believed to be of general interest. The technical matter, in the fields of geology, palæontology, zoology and botany, will follow in a series of illustrated volumes. Twenty-two special papers, based on collections made by the Expedition, have been already published in the Proceedings of the Washington Academy of Sciences, and others will follow. All this material will be brought together in the volumes of the technical series."

Having dealt somewhat fully with the organisation and methods of this truly exemplary expedition, let us now glance briefly over the principal contents of the book, which constitute the best general description of Alaska hitherto published.

The narrative of the cruise by John Burroughs (pp. 1–118) is a piece of literary workmanship such as only an able and well-practised writer with a keen eye for nature and under the stimulus of scenes new to him could have penned. This part will appeal more strongly to the general reader than to the man of science, for to the latter the blending of emotional sentiment with technical description, however skilfully done, can rarely fail to give a sense of incompatibility and distortion. As literature, however, these word-pictures are excellent ; we will quote, as an example, Mr. Burroughs' impression of a distant view of Mount St. Elias (p. 55) :—

"The base and lower ranges had been visible for some time, bathed in clear sunshine, but a heavy canopy of dun-coloured clouds hung above us and stretched away toward the mountain, dropping down there in many curtain-like folds, hiding the peak. But the scene-shifters were at work ; slowly the heavy mass of clouds that limited our view yielded and was spun off by the air-currents till at last the veil was completely rent, and there, in the depths of clear air and sunshine, the vast mass soared to heaven.

"There is sublimity in the sight of a summer thunder-head with its great white and dun convolutions rising up for miles against the sky, but there is more in the vision of a jagged mountain crest piercing the blue at even a lesser height. This is partly because it is a much rarer spectacle, but mainly because it is a display of power that takes greater hold of the imagination. That lift heavenward of the solid crust of the earth, that aspiration of the insensate rocks, that effort of the whole range, as it were, to carry one peak into heights where all may not go—every lower summit seeming to second it and shoulder it forward till it stands there in a kind of serene astronomic solitude and remoteness—is a vision that always shakes the heart of the beholder."

The general narrative is succeeded by a series of profusely illustrated articles on special subjects. First we have "Notes on the Pacific Coast Glaciers," by John Muir (pp. 119–135), who was one of the earliest explorers of the Alaskan ice-fields and is able to compare the present limits of some of the glaciers with their extent in 1879, when he first visited them. He states that in Glacier Bay,

"the Hugh Miller and Muir have receded about two miles in the last twenty years, the Grand Pacific about four, and the Geikie, Rendu and Carrol perhaps from seven to ten miles."

The remaining portion of the first volume (pp. 137–183) is occupied by a concise account of the Indians and Eskimo of the Alaska coast region, by Dr. G. B. Grinnell, closing with the usual lament over the destruction of the weaker race by the influx of the horde of gold-seeking white men, "uncontrolled and uncontrollable."

The second volume opens with a history of the discovery and exploration of Alaska by the veteran Dr. W. H. Dall, whose thirteen previous visits to the territory render him thoroughly qualified to deal with the subject. He treats fully of the early period up to the transference of the country by Russia to the United States in 1867, but sums up the subsequent events in a few sentences, remarking (p. 203) that

"a history of conditions in Alaska from 1867 to 1897 is yet to be written, and when written few Americans will be able to read it without indignation. A country of which it could be said with little exaggeration that

'Never a law of God or man
Runs north of fifty-five' :

a country where no man could make a legal will, own a homestead or transfer it, or so much as cut wood for his fire without defying a Congressional prohibition : where polygamy and slavery and the lynching of witches prevailed, with no legal authority to stay or punish criminals ; such in great part has Alaska been for thirty years."

He notes also :—

"To one conversant with the facts, one of the most amusing things in current literature is the placid innocence of many a casual traveler or gold hunter, who pours out his tale of experiences in the confident belief that nothing of the kind is on record. A bibliography, far from complete, yet with fully 4000 titles, does not cover the publications in books and serials upon the Territory and its adjacent regions."

The next article is on "Days among Alaska Birds," by Mr. Charles Keeler (pp. 205–234), richly illustrated with coloured plates. Many readers will be somewhat astonished to learn that one of the humming-birds is found abundantly as far north as Juneau and Sitka, and will feel with Mr. Keeler that the bird "seemed singularly out of place."

"Indeed, even after reading that the tiny rufous humming-bird journeyed so far into the northern wilds, it was with almost a shock of surprise that we saw the dainty creature, which we

instinctively associate with the tropics, contentedly buzzing about the salmon berries and appearing as unconcerned and happy as if his fine wings had not carried him some thousands of miles from his winter quarters in southern California or Mexico. I cannot imagine a more wonderful instance of bird migration than this—one of the smallest known birds, no larger than a fair-sized moth, yet with strength, endurance, and intelligence to travel up and down the greater part of the North American coast line, pressing close upon the train of early spring, awaiting only the blooming of the wild currant in California and the salmon berry farther north, to venture upon his perilous way!"

What erroneous deductions as to the climate of an "inter-glacial period" would probably be drawn if the remains of a humming-bird were found in a peat bed between deposits derived from glaciers!

The "Forests of Alaska" are described by Prof. B. E. Fernow (pp. 235–256), who points out that their economic value has been much over-estimated. He notes "the astonishing indifference to the influence of the near-by ice-masses" shown by the trees growing in close proximity to some of the great glaciers and even upon their surfaces where covered by moraine material. This article contains some interesting observations on the propagation and spread of forest growth.

The general geography and physiography of the territory are the subject of a lucid article by Mr. H. Gannett (pp. 257–277). In mentioning that the present glaciers are "only trifling fragments" of the great glaciers which occupied this region a short time ago, it is remarked that, nevertheless,

"all the glaciers of Switzerland together would form but a few rivulets of ice on the surface of the Muir Glacier, and the Muir is but one of many glaciers of equal magnitude."

All observers of the glacial phenomena of the region will probably agree with Mr. Gannett that the period since the retreat of the ice from the present water-channels of the coast cannot have been long. It is evident that in Alaska, as in several other glacier-fields of the globe, if the existing ice were entirely removed, few of the glaciers could ever regain their present dimensions under the climatal conditions which now prevail. And it seems probable that in some degree the present glaciers represent the lingering remnants of the great ice-fields of the Glacial period.

"The Alaska Atmosphere" is dealt with by Prof. W. H. Brewer (pp. 279–289), who lays especial stress upon the effects produced by the relatively dustless condition of the air.

An article on "Bogoslof, our Newest Volcano," by Dr. C. H. Merriam (pp. 291–336), copiously illustrated with views of the two new volcanic islands at various periods in their history, and provided with a bibliographical appendix, will appeal to every volcanist.

In describing "The Salmon Industry" (pp. 337–355), which has attained such gigantic proportions in Alaska, Dr. G. B. Grinnell once more calls attention to the wretchedly wasteful methods adopted by the salmon canners in defiance of Congressional laws which there is scarcely a pretence of enforcing, and to the consequent extraordinarily rapid depletion of supplies supposed at first to be inexhaustible. It is the common story of the white pioneer in every part of the globe:—

"All these people recognise very well that they are destroying the fishing; and that before very long a time must come when there will be no more salmon to be canned at a profit. But this very knowledge makes them more and more eager to capture the fish and to capture all the fish. This bitter competition sometimes leads to actual fighting—on the water as well as in the courts. A year or two since, one company which was trying to stop another from fishing on ground which it claimed as its own, sent out its boats with immense seines, and dropping them about the steam launches of its rival tried to haul them to the shore. . . . Thus the canners work in a most wasteful and thoughtlessly selfish way, grasping for everything that is within their reach and thinking nothing of the future. Their motto seems to be, 'If I do not take all I can get somebody else will get something.'"

The final article of the book, however, reveals the pioneer in the unaccustomed *rôle* of conservator. It consists of a highly interesting account, by Mr. M. L. Washburn, of "Fox Farming in Alaska" (pp. 357–365), a new industry which in itself is a striking illustration of western resourcefulness and may lead to important future developments.

"Something like fifteen years ago a few men in western Alaska, realizing that fur-bearing animals were doomed, decided to try the experiment of propagating some of the more valuable kinds. Having resided on the Seal or Pribilof Islands and observed that the blue fox became somewhat tame, they resolved to try its domestication by placing a small number on protected islands and caring for them as the stockman cares for his herd of cattle or sheep. About twenty foxes were taken from St. Paul Island of the Pribilof group, and placed on North Semidi, one of the hundreds of unoccupied islands of Alaska, and thus the experiment began. . . . From North Semidi, the original 'fox-ranch,' if one may employ such a term, foxes were taken to other islands along the Alaska coast and the experiments continued. The results though sometimes discouraging and not always financially successful, have shown on the whole that the animal could be raised and its valuable pelt obtained with as much regularity as in the case of the humbler domestic animals. About thirty islands are now stocked with blue foxes—all the outgrowth of the small stock of twenty foxes taken from St. Paul Island fifteen years ago."

A description is given of one of these ranches where there are now 800 to 1000 foxes. The animals soon learn to recognise their keepers and come to know the feeding time, gathering round for their daily allowance, and afterwards scattering about the island until the time for the next day's dinner. In short, the blue fox has been added to the list of domesticated animals. The probable outcome is thus stated:—

"It is believed that the time is not far distant when hundreds of the now useless islands of Alaska will be utilised in the propagation of fur-bearing animals, and that many of the farmers of the Northern States [*let Canadians take note!*] will have wire-fenced enclosures of an acre or two devoted to this industry, from which they will reap a far greater return than from all the rest of their live stock."

For the excellency of the paper, printing, illustrations and binding, as well as for their contents, these volumes are indeed highly to be commended. As an instance of rare unobtrusiveness and good taste we may mention that in spite of its almost immoderate wealth of illustration not a single portrait of Mr. Harriman or of any member of his family party is to be found in the work.

That the literary and scientific members of this summer cruise should have occasionally burst into song causes us no surprise; and the sprinkling of verse in the volumes is distinctly pardonable in the circumstances.

G. W. L.

OBSERVATIONS OF VOLCANIC ACTIVITY IN THE WEST INDIES.

FURTHER details of the recent volcanic eruptions at Martinique and St. Vincent continue to reach us through West Indian and other papers. Though the great eruptions of Mont Pelée and the Soufrière occurred on May 7–8, the *Dominica Guardian* states that shocks of earthquake were felt so far back as February of last year. These disturbances were noticed several times during the year, and were regarded as serious in February of this year. From April 20 also until the eruption, rumbling sounds were frequently heard, especially at Fancy and at Frasers. Nineteen shocks were experienced within half an hour on May 3 at Wallibou,

and the disturbances became more noticeable as the days went on, until, on May 5, the Soufrière gave definite warnings of its renewed activity. The Rev. J. H. Darrell, writing from Kingstown, St. Vincent, on May 9, gives, in the *Dominica Guardian*, the following account of the subsequent eruptious of this volcano:—

It was on Tuesday, May 6, at 3 p.m., that the mountain commenced its series of volcanic efforts. A strong shock of earthquake, accompanied by a terrible noise, occurred, and the volcano began to emit steam. At 5 p.m. louder and more frequent explosions were heard, the detonations succeeding each other at rapidly diminishing intervals. At 7.30 p.m. columns of steam issued from the old crater with terrific noise. These lasted until midnight, when another heavy explosion occurred.

At 7 a.m. on Wednesday, May 7, there was another sudden and violent escape of pent-up steam, which continued ascending until 10 a.m., when other material began to be ejected. It would seem that this was the time when the enormous mass of water in the lake of the old crater was emitted in a gaseous condition. By 12 o'clock noon it appeared that there were three craters vomiting lava—the old crater that had contained the lake, the second crater that opened in 1812, and a third crater that had burst open in the present eruption. Six distinct streams of lava were visible, running down the sides of the mountain. The mountain heaved and laboured to rid itself of the burning mass of lava heaving and tossing below. By 12.30 p.m. it was evident that it had begun to disengage itself of its burden by the appearances as of fire flashing now and then around the edge of the crater. There was, however, no visible ascension of flame. These flame-like appearances were, I think, occasioned by the molten lava rising to the neck of the volcano. Being quite luminous, the light emitted was reflected from the banks of steam above, giving them the appearance of flame.

From the time the volcano became fully active, tremendous detonations followed one another so rapidly that they seemed to merge into a continuous roar which lasted all through the night of May 7 and up to 6.30 a.m. on May 9. These detonations and thunderings were heard as far as Barbados, 100 miles distant, as well as in Grenada, Trinidad and the south end of St. Lucia. At 12.10 p.m. I left in company with several gentlemen in a small row boat to go to Chateaubelair, where we hoped to get a better view of the eruption. As we passed Layou, the first town on the leeward coast, the odour of sulphuretted hydrogen was very perceptible. Before we got half way on our journey a vast column of steam, smoke and ashes ascended to a prodigious elevation. The majestic body of curling vapour was sublime beyond imagination. We were about eight miles from the crater, as the crow flies, and the top of the enormous column, eight miles off, reached higher than one-fourth of the segment of the circle. I judge that the awful pillar was fully eight miles in height. We were rapidly proceeding to our point of observation, when an immense cloud, dark, dense, and apparently thick with volcanic material, descended over our pathway, impeding our progress and warning us to proceed no further. This mighty bank of sulphurous vapour and smoke assumed at one time the shape of a gigantic promontory, then appeared as a collection of twirling, revolving cloud-whirls, turning with rapid velocity, now assuming the shape of gigantic cauliflowers, then efflorescing into beautiful flower-shapes, some dark, some effulgent, others pearly white, and all brilliantly illuminated by electric flashes. Darkness, however, soon fell upon us. The sulphurous air was laden with fine dust that fell thickly upon and around us discolouring the sea; a black rain began to fall, followed by another rain of favilla, lapilli and scoriæ.

The electric flashes were marvellously rapid in their motions and numerous beyond all computation. These with the thundering noise of the mountain mingled with the dismal roar of the lava, the shocks of earthquake, the falling of stones, the enormous quantity of material ejected from the belching craters, producing a darkness as dense as a starless midnight, the plutonic energy of the mountain growing greater every moment combined to make up a scene of horrors. It was after five o'clock when we returned to Kingstown, cowed and impressed by the weirdness of the scene we had witnessed, and covered with the still thickly falling grey dust. Of what this material is composed I am unable to give a certain opinion; but it appears to consist of comminuted rock, produced by attrition of the material as in successive outbursts it is hurled aloft and then tumbles back again to the burning crater to be ejected finally as impalpable dust. So minute are the particles that they find their way through the finest chinks of a closed room. Large areas of cultivation have been buried under the fall of the dust. Its effects upon vegetation will probably be beneficial ultimately, but in the meantime great suffering as well as inconvenience is occasioned thereby. The awful scene was renewed yesterday (May 8) and again to-day. At about 8 a.m. the volcano shot out an immense volume of material which was carried in a cloud over Georgetown and its neighbourhood, causing, not only great alarm, but compelling the people by families to seek shelter in other districts.

More than 400 lives have been lost on the windward side of the island, chiefly from lightning, and we have not yet heard from other parts of the island in that neighbourhood. The flowing lava on the leeward side of the mountain has buried up the Wallibou and Richmond villages and estates, while on the windward side of the mountain the estates of Lot Fourteen, Rabacca, Overland, Tourama, Orange Hill, Mount Bentinck, Langely Park and portions of others have been obliterated.

It is now 2 p.m. (May 9). A dense gloom still envelops the mountain, but there has been no further eruption since 8 a.m. Several streams and rivers have dried up in various parts of the island, and we are threatened with a water as well as a food famine.

As already announced, the National Geographic Society of Washington has sent a special expedition to Martinique and St. Vincent to investigate the volcanic conditions of the West Indian regions. The members consist of Mr. Robert T. Hill, of the U.S. Geological Survey; Prof. Israel C. Russell, professor of geology in the University of Michigan, Ann Arbor; Commander C. E. Borchgrevink, the Antarctic explorer; Dr. T. A. Jaggar, of Harvard University; Mr. G. C. Curtis, of Cambridge, U.S.A., and Dr. Angelo Heilprin, president of the Philadelphia Geographical Society.

The expedition is one of the most important and best equipped commissions ever sent out to study actual volcanic action. Results of scientific and practical consequence may therefore be expected from the work of the members of the party. On their return to the United States they will report the results of their observations to the National Geographic Society. This report, forming a series, will be published in full in the journal of the Society, the *National Geographic Magazine*, the June number of which contains a preliminary account of the observations already made.

Upon arriving at Martinique, Dr. Hill embarked on a steamer and examined the coast as far north as Macouba Point, the north end of the island, making frequent landings. After landing at Le Prêcheur, a little village five miles north of St. Pierre, he walked through an area of active volcanism to the destroyed city. Dr. Hill, according to the Associated Press despatches from Fort de France, was the first man to set foot in the active area of craters, fissures and fumaroles.

On his return to Fort de France he issued a brief statement as to his observations to the National Geographic Society, and it is here abriged from the Society's magazine.

The zone of the catastrophe in Martinique forms an elongated oval, containing on land about eight square miles of destruction. This oval is partly over the sea. The land part is bounded by lines running from Le Prêcheur to the peak of Mont Pelée, thence curving around to Carbet. There were three well-marked zones:—

(1) A centre of annihilation, in which all life, vegetable and animal, was utterly destroyed. The greater northern part of St. Pierre was in this zone.

(2) A zone of singeing, blistering flame, which also was fatal to all life, killing all men and animals, burning the leaves on the trees, and scorching, but not utterly destroying, the trees themselves.

(3) A large outer, non-destructive zone of ashes, wherein some vegetation was injured.

The focus of annihilation was the new crater, midway between the sea and the peak of Mont Pelée, where now exists a new area of active volcanism, with hundreds of fumaroles, or miniature volcanoes.

The new crater is now vomiting black, hot mud, which is falling into the sea. Both craters, the old and new, are active. Mushroom-shaped steam explosions constantly ascend from the old crater, while heavy ash-laden clouds float horizontally from the new crater. The old one ejects steam, smoke, mud, pumice and lapilli, but no molten lava.

The salient topography of the region is unaltered. The destruction of St. Pierre was due to the new crater. The explosion had great superficial force, acting in radial directions, as is evidenced by the dismounting and carrying for yards the guns in the battery on the hill south of St. Pierre and the statue of the Virgin in the same locality, and also by the condition of the ruined houses in St. Pierre.

According to the testimony of some persons, there was an accompanying flame. Others think the incandescent cinders and the force of their ejection were sufficient to cause the destruction. This must be investigated.

On Monday, May 26, Dr. Hill started on horseback from Fort de France for Morne Rouge and Mont Pelée. He reached Morne Rouge safely on May 27, where he succeeded in getting a number of photographs. A close approach to Mont Pelée was impossible, so he started back in a southerly direction. During the two nights he was camping out he made some important observations of volcanic action, and on his return issued the following statement:—

My attempt to examine the crater of Mont Pelée has been futile. I succeeded, however, in getting very close to Morne Rouge. At 7 o'clock on Monday evening I witnessed from a point near the ruins of St. Pierre a frightful explosion from Mont Pelée, and noted the accompanying phenomena. While these eruptions continue no sane man should attempt an ascent to the crater of the volcano. Following the salvos of detonations from the mountain, gigantic mushroom-shaped columns of smoke and cinders ascended into the clear, starlit sky, and then spread in a vast black sheet to the south and directly over my head. Through this sheet, which extended a distance of ten miles from the crater, vivid and awful lightning-like bolts flashed with alarming frequency. They followed distinct paths of ignition, but were different from lightning, in that the bolts were horizontal and not perpendicular. This is indisputable evidence of the explosive oxidation of the gases after they left the crater. This is a most important observation, and it explains in part the awful catastrophe. This phenomenon is entirely new in volcanic history.

I took many photographs, but do not hesitate to acknowledge that I was terrified.

Nearly all the phenomena of these volcanic outbreaks are new to science, and many of them have not yet been explained. The volcano is still intensely active, and I cannot make any predictions as to what it will do.

Associated Press messages from Martinique, dated May 31, announced that Prof. Heilprin had succeeded in climbing to the top of the crater of Mont Pelée. The despatch is as follows:—

Prof. Angelo Heilprin this morning ascended to the top of the crater on the summit of Mont Pelée.

The expedition left Fort de France last Thursday, May 29, at noon. Friday was spent in studying the newly formed craters on the north flank of the mountain. Saturday morning Prof. Heilprin determined to attempt the ascent to the top of the crater, and with this purpose in view he set out at five o'clock.

The volcano was very active, but Prof. Heilprin reached the summit and looked down into the huge crater. Here he spent some time in taking careful observations. He saw a huge cinder cone in the centre of the crater. The opening of the crater itself is a vast crevice 500 feet long and 150 feet wide.

While Prof. Heilprin was on the summit of the volcano, several violent explosions of steam and cinder-laden vapour took place, and again and again his life was in danger. Ashes fell about him in such quantities at times as to obscure his vision completely.

Prof. Heilprin found that the crater at the head of the River Fallaise has synchronous eruptions with the crater at the summit of the volcano, and that it ejects precisely the same matter at such times.

On May 31 a party consisting of Prof. Jaggar, of Harvard University, Dr. Hovey, of the American Museum of Natural History of New York, and Mr. George C. Curtis, ascended to the summit of the Soufrière of St. Vincent from the western side.

The ascent was exceedingly difficult, owing to the mud that covered the mountain side, but the ground was cold. After a tiresome scramble up the slippery hill, the rim of the old crater was reached about midday. There was no trace whatever of vegetation, but there had been no change in the topographical outlines of the mountain on that side, and the old crater retained its tragic beauty. The great mass of water that formerly lay serenely about 500 feet below the rim of the crater had disappeared, and the crater appeared to be a dreadful chasm more than 2000 feet deep. With the aid of a glass, water was made out at the bottom of this abyss.

The party did not venture across the summit of the Soufrière to inspect the new crater, which was then emitting a little vapour, for the ground in that direction looked to be dangerous.

Apparently the ridge of the mountain, called "The Saddle," was intact, although the old crater seemed of larger circumference than before the recent eruption. At the western base of the Soufrière a subsidence of a depth of 100 feet occurred for an area of a square mile. The bank of volcanic dust that prevents the sea encroaching farther inland at Wallibou is being gradually washed away. The lava beds on the eastern side of the Soufrière continue to emit steam, despite the protracted and heavy rainfall that has occurred.

Mr. Knight, Senator for Martinique, has arrived in Paris, and a few of his observations of the condition of men and things in that island are given in yesterday's *Times*. He says that the streams of mud which are still flowing do not emerge from the flanks of the volcano, but from the constantly convulsed ground, now opening in large abysses and then closing. Evidence that the death of the victims of the Mont Pelée eruption must have been instantaneous was obtained from the appearance of the bodies discovered.

Thus, persons have been found on the thresholds of their nearly demolished houses in the attitude of gazing at Mont Pelée. Others were found seated at a table. One man, discovered in the middle of the street, had the muscles of his legs and arms fixed in the attitude of a runner. Others were shaking hands.

PROF. ADOLF FICK.[1]

WITH Adolf Fick, the physiologist of Würzburg, whose death took place in the autumn of last year at Blankenberg, there passed away one of the last representatives of the brilliant physiological school by the combined labours and critical acumen of which, during the latter half of the past century, the foundations of modern physiology were established. For the complete appreciation of the man's whole character, however, regard should be had as well to Adolf Fick's energetic and practical support of public, and, in particular, educational questions, as to his distinction as investigator, man of science and teacher. In all matters that he took in hand he made a striking and original appearance, and he merits a special place in the honour roll of history.

Fick, in whom as a youth conspicuous mathematical talent had already displayed itself, sought the university with the intention of studying mathematics. His elder brother, Heinrich, who died a few years ago while professor of Roman law at Zürich, urged him to the study of medicine, and this he pursued at Marburg and Berlin.

[1] Abridged from an obituary notice by Prof. Kunkel.

At the former university he graduated in September 1851. As early as the year 1852 he worked as prosector under C. Ludwig, whose close friendship he retained throughout life.

In 1856 he went into residence at Zürich, and, in succession to Ludwig and Moleschott, obtained in 1862 the full professorship of physiology there, which he retained for six years. In the year 1868, upon Von Bezold's early death, Fick was called to Würzburg, where he filled the chair of physiology for thirty-one years. He resigned his post at the end of the summer term of 1899, not from distaste for work or through the burden of years, but while in full vigour of mind and body, in the strict fulfilment of a long-expressed intention of making way, on the completion of his seventieth year of life, for the energies of a younger man.

At the time when Fick entered upon the study of physiology, modern medicine, as it is now understood and taught in the schools, was still in its infancy. The great strides made by chemistry at the beginning of last century had rendered possible the introduction of exact methods in the investigation of the problems of biology. The first positions securely gained by physical science had been at once utilised to set aside the doctrine of "vital power," and to establish the important principle that we must endeavour to explain the specific phenomena of life as being determined by preceding chemical and physical conditions. Just as the chemists Lavoisier, Liebig and others, with the knowledge that they had won by their special training, addressed themselves at once to the solution of biological questions, so a school of physicists, starting from the basis of its own discoveries, proceeded to the investigation of the physiological problems which appertained to it. The brothers Ernst, Heinrich and Eduard Weber, Helmholtz, Du Bois-Reymond, Ludwig, Brücke, are the most prominent names of this school and already belong to history, and amongst these earlier adaptors of the methods of physical research to the study of biology, Fick must be accorded a place on account both of his conspicuous bent and training as a physicist and of the work accomplished by him. So early as the year 1849, when a nineteen-year-old student, Fick published his first scientific treatise—that on the muscular system of the thigh—an essay which even at the present day forms a very instructive analysis of the mechanical relations of the muscles of the hip joint. For these researches into the mechanism of the human body Fick always retained a liking. He wrote a monograph on the saddle-shaped articulations, gave in his "Medical Physics," the first edition of which appeared in the year 1856, an admirable exposition of the mechanism of the joints generally, and contributed an article on the subject to L. Hermann's great "Handbuch," besides encouraging several of his own pupils to undertake similar investigations.

His scientific work upon the mechanics of the body led Fick to a special line of inquiry—one to which he devoted the working time and energy of his mature years—that respecting the changes of muscle during its contraction. There are about thirty essays by Fick himself, as well as a number of writings by his students, which deal with particular points in the physiology of muscle. Of these one of the most important was the development of heat which attends contraction. With the aid of thermo-electrical apparatus devised by himself, he was enabled to determine approximately the absolute amount of heat that was developed during continuous contraction. He subsequently introduced and defined the important conceptions which are expressed by the terms "isotonic" and "isometric" as applied to contraction, and investigated the nature of the conditions so designated. For the measurement of work, he constructed his "Arbeitssammler."

As the final result of all his muscular studies, he stated his views as to the nature of the process of muscular contraction. These have not escaped criticism. One of his conclusions, however, which in a manner he reached by a process of exclusion in so far as he rendered untenable other possible ways of explaining the contraction of muscle by reference to the second of the laws of the mechanical theory of heat, is, indeed, of quite prime importance.

According to Fick, the kinetic energy generated by chemical reactions in the muscle cannot be accounted for by the hypothesis that the chemical energy consumed is first developed in the form of heat, and this transformed into the coordinated kinetic energy of the contraction. It must rather be supposed that the chemical forces stored up in the muscle are so coordinated that in their transformation into kinetic energy they directly cause the change of form of the muscle; so that we have not to do with a thermodynamic process as in the case of the steam engine, but the chemical energy is converted directly into the coordinated kinetic energy of the contraction. With this notable definition respecting the changes which precede muscular contraction, an important stage is reached in the explanation of the phenomena of contractile substances, and every future discussion of these questions must be referred back to this as a starting point.

Another subject of Fick's repeated investigations was that of the dynamics of the circulation. His first efforts were directed towards improving the methods of obtaining graphic records of the blood-pressure curve, with the result that the manometer and the spring kymograph bearing his name have been adopted into general use. He was the first to analyse by means of an apparatus constructed by him—now called the plethysmograph—and with the greatest clearness and precision, the variations in speed of the flow of blood in artery and vein (Zürich Laboratory Reports, 1868). By means of new methods of investigation and observation he threw valuable light upon the phenomenon of dicrotism and upon the pressure of the blood in the ventricles of the heart and in the great vessels.

Under the head of the physiology of the organs of sense, he paid special attention to the subject of vision. His dissertation "Tractatus de errore optico," &c., Marburg, 1851, deals principally with the phenomena of astigmatism (Helmholtz, "Physiolog. Optik," p. 147). Fick occupied himself repeatedly with speculations as to the explanation of the colour sense. He published a number of critical and experimental studies upon the subject. His last communication to the Society of Medical Physics of Würzburg dealt with Hering's theory of the colour sense. His contributions to the study of the subject of hearing consisted in an experimental investigation upon the mechanism of the tympanum. A paper by Fick, on the sense of touch, is comprised in the volume for 1860 of Moleschott's *Untersuchungen*.

Upon the physiology of the nerve substance Fick published only a few essays. To the issues for the year 1862 and 1864 of the reports of the Vienna Academy and to the E. H. Weber "Festschrift" in the year 1871 he contributed studies upon the sensibility of the spinal chord. The essay upon the different degrees of excitability observable in functionally different parts of the chord deserves special mention.

Of Fick's work on metabolism, and the physiology of the digestive glands, may be mentioned, as particularly well known, the experiment[1] that he made with the

[1] *Vide* the *Philosophical Magazine* for June 1866. The late Sir Edward Frankland regarded this as "one of the most important chemico-physiological experiments ever made" (Frankland's "Experimental Researches," p. 918). Although prevented from accompanying his brother-in-law, Fick, on the expedition, Frankland undertook the experimental determination of certain calorimetrical equivalents required as a basis for the conclusions drawn from the Faulhorn experiment. These, it may be added, had a much wider application, and until replaced by more exact determinations they served for years as the only data on which calculations could be founded.

cooperation of J. Wislicenus for estimating the amount of albumin expended in physical work such as mountain climbing. The result, that the material used in muscular work must be free from nitrogen, was at once generally accepted. The results of investigations on the peptones, upon what becomes of them in the circulation of the blood, on the action of pepsin, and on the value of various nutritive substances, were made public from time to time in lectures for which Fick prepared and demonstrated very numerous and laborious experiments.

The students' manuals which Fick wrote are distinguished by their lucid exposition, clear style and critical discussion. His first book, entitled "Die medicinische Physik," was written when he was in his twenty-seventh year, and passed through three editions. This book at once secured for the young author a place in the front rank of the physiologists of the day. Of the "Kompendium der Physiologie" four editions appeared, the last in the year 1892.

As early as 1862 he published a "Lehrbuch der Anatomie und Physiologie der Sinnesorgane" as part of a larger compilation. To Hermann's "Handbuch," already mentioned, he furnished two elaborate articles on physiological optics.

From the physiological laboratory at Zürich in the year 1869, and from the Würzburg Institute in the years 1873 to 1878, there appeared the "Physiologische Untersuchungen" (four issues). From 1852 and onwards for fourteen years he was one of the contributors to Canstatt's "Jahres bericht" on the literature of physiology.

Of the remarkable talents and training that enabled him, for instance, to deliver experimental lectures on physics during the vacancy of the chair of physics, he also gave evidence by his own productions as investigator and writer in this branch of science. Best known is his work on hydro-diffusion in Poggendorff's *Annals*. The fundamental conceptions of mechanics, and the insight gained into these by means of the mechanical theory of heat, were favourite subjects of his speculation. A brief enumeration must suffice here of the titles of the most characteristic of the treatises that fall under this head, and many of which lie in the borderland between physics and pure philosophy:—

"Ueber die der Mechanik zu Grunde liegenden Anschauungen," "Ueber die Zerstreuung der Energie," "Versuch einer physischen Deutung der kritischen Geschwindigkeit in Weber's Gesetz," "Ueber Druck im innern von Flüssigkeiten." The following treatises belong more to the philosophical side:—"Die Naturkräfte in ihrer Wechselwirkung," "Die Welt als Vorstellung," "Philosophischer Versuch ueber die Wahrscheinlichkeit," "Die stetige Raumerfüllung durch Masse," &c.

Even this slight sketch of Fick's literary activity will show how comprehensively he mapped out for himself the sphere of his work and how exhaustively he laboured in it. But he was also unusually well equipped in all other departments of human knowledge. He was extraordinarily learned and well read. In accordance with his own definition of an educated man as one who is capable of taking a comprehensive view of the most characteristic results furnished by the intellectual work of the whole of mankind, Fick studied and mastered a very widely embracing province of knowledge. He was assisted in his efforts by a particularly accurate memory, which he retained unimpaired to the last.

Conspicuous among Fick's talents was his critical faculty. He dealt with the first principles of the science of mechanics in an unusually clear and distinct way, and when a series of novel conceptions was put before him he was able to correctly analyse and estimate them. He was recognised by those who knew him as a scientific critic by vocation. He was aided in his experimental work by great manual dexterity. He prided himself upon belonging to the school of Bunsen, and in the construction of the various instruments which he introduced followed Bunsen's method by himself putting together out of simple materials the first models of new scientific apparatus. It is an interesting fact that Fick warmly espoused the cause of total abstinence, and was himself for the last decade of his life a total abstainer.

NOTES.

M. AMAGAT has been elected a member of the section of physics of the Paris Academy of Sciences, in succession to the late Prof. Cornu.

MR. MARCONI brought forward two interesting pieces of information in his lecture at the Royal Institution last Friday. The first relates to the new form of magnetic detector which he has been employing in place of the coherer. The instrument is found to be more sensitive and trustworthy than the coherer, and gives promise of a great increase in the speed of working. Already a speed of thirty words a minute has been attained, and this may possibly be increased to several hundred. The second point relates to the recent Transatlantic signalling. It seems that on the occasion of Mr. Marconi's journey across the Atlantic in the *Philadelphia*, the signals transmitted during the day failed entirely at a distance of 700 miles, although a message was successfully sent at night more than 1550 miles, and a signal more than 2000 miles. This effect Mr. Marconi suggests may be due to the diselectrification of the aërial wires by the daylight. The difficulty can, however, be got over by the use of greater transmitting power—as is evidenced partly by the fact that the signal received at Newfoundland was transmitted during the daytime. The Canadian station, for the erection of which Mr. Marconi was liberally subsidised by the Canadian Government, will be open shortly for experiments. The rest of the lecture gave an interesting *résumé* of the work already accomplished, but contained nothing which will be new to those who have followed its progress.

THE eighty-third meeting of the Société Helvétique des Sciences Naturelles will be held at Geneva on September 7–10. M. E. Sarasin is the president of the society, M. Marc Micheli and Prof. R. Chodat vice-presidents, M. Maurice Gauthier and M. A. de Candolle secretaries, and M. A. Pictet treasurer. Correspondence referring to the forthcoming meeting should be addressed to M. de Candolle, Cour de St. Pierre, 3, Geneva.

IN accordance with previous announcements, the autumn meeting of the Iron and Steel Institute will be held at Düsseldorf on September 3–4. The directors of the Norddeutscher Lloyd have generously offered to the members attending the meeting complimentary first-class passages, including table, to the number of 250, by the s.s. *Kronprinz Wilhelm*, upon that ship's homeward voyage (from New York) to Bremen, on September 1, from Plymouth. The provisional programme of the meeting is as follows:—On Tuesday, September 2, the members will arrive at Düsseldorf. On September 3 the president, council and members will be received by the civic authorities and by the reception committee in the Municipal Concert Hall (Städtische Tonhalle). A selection of papers will subsequently be read and discussed. In the afternoon a visit will be paid to the Düsseldorf Exhibition, for the purpose of examining the various sections of mining, metallurgy and machinery. In the evening the members and ladies accompanying them will be invited by the Mayor and Corporation of Düsseldorf to a conversazione and concert. On September 4 the morning will be devoted to the reading and discussion of papers, and the afternoon to visits to the exhibition and to works in the immediate vicinity. In the evening the reception committee will entertain the visitors at a banquet.

On September 5 the whole day will be devoted to visits to works. In the evening the exhibition grounds will be specially illuminated in honour of the Institute. On September 6 there will be an excursion to the picturesque district of Vohwinkel, to the Elberfeld suspended railway and to the Kaiserbridge, near Müngsten. A detailed programme will be issued when the arrangements are further advanced.

ON June 14 the Essex Field Club visited those portions of the old Lambourne and Hainhault Forests which, according to the scheme proposed by Mr. E. N. Buxton, are to be re-afforested and to become an open space for London second only in importance to Epping Forest. It is proposed to make free some 859 acres, of which seventy are detached from the main portion. These form Grange Hill Forest, and the purchase of them for 7000*l.* is now assured. For the rest, 20,000*l.* is asked. It is hardly necessary to point out the importance from a natural history point of view which the grounds will possess if they become public property. Not only will the naturalist find happy grounds for study, but others who feel the necessary primness of London parks will be able to enjoy nature less adorned.

QUEENWOOD COLLEGE, near Stockbridge, Hants, was destroyed by fire on June 10, Mr. Charles Willmore, the principal, meeting his death in the disaster. Several distinguished men, both in Mr. Willmore's time and in that of his predecessor, Mr. George Edmondson, made their temporary home at Queenwood. Prof. Fawcett, Postmaster-General and political economist, was a scholar there; and in the roll of its science masters we find the names of Tyndall, Frankland, Debus, Field and Hake. There have been few schools in this country in which the pursuit of science was more earnestly and heartily encouraged. It is now about seven years since the college, as such, ceased to exist.

DURING a trial with a French naval balloon off Toulon on June 9, Lieut. Baudic, who was alone in the car, was thrown into the sea and drowned. The object of the ascent was to ascertain whether it is possible, from the car of a balloon, to perceive submarine boats at a distance of a mile or so. The balloon started from the Maritime Aëronautical Works established in 1890 at Garrouban. The Garrouban Aëronautical Station is provided with two balloons, the *Auxiliare*, and a larger one measuring 500 c.m. capable of carrying three persons, called the *Normal*. These marine balloons are intended to be sent up captive from a large war steamer for inspecting the surrounding sea and sending up signals at a distance.

WE learn from *Science* that at the recent annual meeting of the American Academy of Arts and Sciences it was decided to award the "Rumford premium" to Prof. George E. Hale, of the Yerkes Observatory, "for his investigations in solar and stellar physics, and in particular for the invention and perfection of the spectro-heliograph." It was also resolved to grant the sum of 750 dollars from the income of the Rumford fund to be expended for the construction of a mercurial compression pump designed by Prof. Theodore W. Richards and to be used in his research on the Thomson-Joule effect. A grant from the Rumford fund was also made to Prof. Arthur A. Noyes in aid of his research as to the effect of high temperatures upon the electrical conductivity of aqueous solutions.

THE *Times* reports that the jubilee festival of the Germanic Museum at Nuremberg was celebrated on Monday in the presence of the German Emperor and Empress and members of the Royal Houses of Bavaria, Baden and Würtemberg. The collections in the museum illustrate every aspect of the growth of the Germanic peoples; special collections, for example, have been formed to illustrate the development of the trade guilds and of characteristic German industries, such as the Bavarian breweries. From a collection of antiquities in the narrow sense of weapons, heraldic devices and the like, the museum has grown into a complete historical exhibition.

DURING the researches of the seventh expedition of the Liverpool School of Tropical Medicine, which visited the Gambia in the summer and autumn of last year, a new parasite associated with symptoms resembling those occurring in animals suffering from the tse-tse fly disease was found in the blood of a native child. The committee of the school has now resolved to despatch a new expedition to the Gambia and to Senegambia to study the disease further. The expedition, which will start in a few weeks, will, as at present organised, consist of Dr. J. Everett Dutton and Dr. J. L. Todd, of McGill University, Montreal. Its principal object will be to investigate the conditions under which the disease occurs in both Europeans and natives and its distribution, and also to ascertain how it is conveyed from man to man.

AMONG the subjects discussed at the annual meeting of the Sea Fisheries Committees of England held in London on June 10 and presided over by Mr. Gerald Balfour were the establishment and maintenance by the Government of one or more laboratories for carrying on the work of fishery research, or, failing that, the provision from Imperial resources of the funds necessary to render more efficient and useful the laboratories which at present exist. Mr. Gerald Balfour, in welcoming the delegates, said some of the subjects discussed last year, such as the registry, lettering and numbering of fishing boats, had been carried out; and the artificial fertilisation of ova had been referred to the Committee on Ichthyological Research now sitting, as was also the establishment and maintenance of laboratories and hatcheries.

IN the popular mind, the medical and other sciences are regarded as too severely precise to have romantic aspects, yet in the history of scientific discovery records can be found of many noble deeds and sacrifices for the sake of others. Sir Frederick Treves referred to the romance of medicine in an address at the Charing Cross Hospital Medical School on June 11. He remarked that the exploits of discoverers of new countries had always been surrounded with a halo of romance, but the discoveries in medicine had not been less romantic. No story of the past could exceed the romance of the history of the work of Pasteur, Lister and Koch. They had not discovered any new garden of the Hesperides, but they had travelled far into the valley of the shadow of death. He did not think there was anything in the history more tragic than the account of Laënnec holding on the point of a needle a minute scrap of tissue and saying "I have found the seed of tuberculosis." When Koch demonstrated the bacillus of tuberculosis he was practically reaching one of the limits of philosophic inquiry. Could there be anything more profoundly interesting than the way in which malaria was studied and finally explained?

SEVERAL matters of meteorological interest have been recorded during the past few days. The drought in Australia came to an end at the beginning of last week, when good rains occurred in portions of South Australia, New South Wales and Victoria. Less hopeful news comes, however, from India, for an Exchange telegram from Simla states that the official monsoon forecast, which this year for the first time is withheld from the public, foreshadows a deficient rainfall all over India and drought in Gujerat and Western Punjab. At Karachi, however, a terrific storm occurred on Monday. The *Daily Mail* states that the city is half submerged by extraordinarily high tides. Telegraphs and telephones have all been destroyed, and there has been serious loss of life and property. Exceptionally stormy weather is also being experienced in South Africa. At Middleburg,

Cape Colony, for the first time for sixteen years, the town was covered with deep snow on June 11. Storm and cold are general throughout the Colony. The cold is unprecedented, and thousands of cattle and sheep have perished. In many places the telegraph poles are buried beneath snowdrifts. A very severe snowstorm swept ever the midland districts of Cape Colony on June 14. Trains were blocked at Naauwpoort by a snowdrift 6 feet in depth, and much difficulty was experienced in clearing the lines. Heavy falls of snow also occurred in other parts of the country.

THE annual report of the Decimal Association records that ately there has been a very decided growth of public opinion in favour of the compulsory adoption of the metric weights and measures throughout the British Empire. There are warm supporters of the reform in Canada, Australia, Cape Colony and India, and efforts will be made to bring the question before the Conference of Colonial Premiers to be held at the time of the Coronation. British consuls abroad, residing in countries where the metric system is in use, continue to dwell upon the importance of the change being made from our present confused and complicated weights and measures to those of the metric system. The Committee on Decimal Coinage appointed by the Federal House of Representatives for Australia issued its report in April recommending the adoption of decimal coinage. The report of this committee concluded with a recommendation that the Commonwealth should cooperate in any movement for the decimalisation of the weights and measures of the Empire. Quite recently the Association of Trade Protection Societies of the United Kingdom passed the following resolution at its annual meeting :—"That this meeting is of opinion that the time has now arrived when the decimal system of coinage and the metric system of weights and measures should be compulsorily adopted throughout the British Empire."

AMERICA has just furnished a new high-speed record, which has been attained on the Burlington and Missouri Railroad. The train (says *Feilden's Magazine* for June) consisted of nine cars, namely, a mail car, a luggage car, two reclining chair cars, three sleeping cars, dining car and a private car, and the engine (B. and M. R. No. 41) was of the ten-wheeled type with 6-feet driving wheels. The section over which the record was taken was between Eckley and Wray, Colorado, separated by a distance of 14·8 miles, which was "covered in exactly nine minutes, that is, the train was travelling at the rate of 98·66 miles per hour for the whole section." It is stated that the time was correctly tallied by five separate chronographs, and may therefore be considered trustworthy.

IN the *Jahrbuch der k.-k. geol. Reichsanstalt* (Band li. Heft 1), Herr Lukas Waagen contributes a detailed account of the Jurassic *Avicula* (*Oxytoma*) *inaequivalvis* and its allies. This paper will be welcomed by all who may have occasion to study this very variable and difficult group of shells. The author supplies a comprehensive synonymic list, and concludes that the numerous specific separations in this group, proposed by various authors, are in reality unwarranted.

A SCORE of new forms of fossil ear-bones of fishes, from the Tertiary strata of Austro-Hungary, have been described by R. J. Schubert (*Jahrbuch der k.-k. geol. Reichsanstalt*, Band li. Heft 2). These otoliths are for the most part referred to Umbrina, Corvina, Sciænidarum and Sciæna, and were obtained in Pliocene deposits at Brunn am Gebirge and in Miocene beds at several other localities. Some appear to indicate relationship with recent Mediterranean forms, while others have their nearest allies in the Oligocene and Miocene of Germany and in the older Tertiaries of North America. The paper is well illustrated.

IN a memoir on the flora of Thibet or high Asia Mr. Botting Hemsley, F.R.S., has compiled an account which brings out vividly the unique conditions of altitude and climate. The data for the subject-matter are obtained from collections deposited in the herbarium at Kew. Amongst the peculiarities of the vegetation may be noted the scarcity of certain types of plants, *e.g.* annuals, succulents and bulbous plants (except *Allium Semenovi*, which is widely distributed). Woody plants, too, are rare and poorly developed.

WE have received the Report of the South London Entomological and Natural History Society for 1901.

THE most interesting item in the Report of the Albany Museum for the year 1901 is the identification among the collection of a pair of horns of the blaauwbok (*Hippotragus leucophoeus*), an antelope formerly found in the neighbourhood of Cape Town which has been extinct for considerably more than a century. The horns were entered in one of the old catalogues as belonging to the animal in question ; assuming the identification to be correct, the specimen appears to be the only known relic of the blaauwbok remaining in South Africa.

IN the *American Naturalist* for May, Prof. H. F. Osborn further elaborates his views as to the "law of adaptive radiation" among mammals. One result of his investigations is to explode the old idea that it is possible to reconstruct an extinct animal from either a claw or a tooth. Correlation is not, as Cuvier supposed, morphological, "but physiological, function always preceding structure. It becomes closest when teeth and feet combine in the same function, as in the prehensile canines and claws of the Felidæ, and most diverse where the functions are most diverse, as in the teeth and paddles of the Pinnipedia."

VOL. liii. of the *Anales* of the Scientific Society of Argentina contains a long memoir, by Señor A. Gallardo, of the late Dr. C. Berg, director of the museum at Buenos Aires. From this it appears that Berg was born at Tuckum, Curlandia, Russia, in 1843, and that, after much good work in his native country, he first visited Argentina in 1873. Here, under the auspices of Burmeister, he worked at the entomology and botany of the country assiduously for nearly two years, when he was appointed professor of zoology at Cordoba. This appointment, however, he held but two months, as in March, 1875, he was elected to the chair of natural history at the National College of Buenos Aires, in succession to Dr. J. Ramorino. In 1890 he was specially entrusted with the reorganisation of the National Museum at Monte Video, and on the death of Burmeister in 1892 he succeeded to the directorship of the National Museum at Buenos Aires, a post which he held until his own death. Berg's work covered a very wild field both in zoology and botany, and an appendix to the memoir before us contains a very long list of papers of which he was the author. One of his latest contributions proved the distinctness of the smaller form of mara, or Patagonian cavy, the *Dolichotis salinicola* of Burmeister. He is succeeded in the directorship of the museum by Dr. Florentino Ameghino, so well known on account of his remarkable contributions to the history of the extinct vertebrate fauna of Patagonia.

CURIOUS if true must be the verdict in regard to a paper contributed by Prof. William Patten to the May issue of the *American Naturalist* on the structure and classification of the Tremataspidæ. This family is represented by a single genus and species (*Tremataspis schrenki*), all the known remains of which have been obtained from the Lower Silurian of a small pit at Rootsikuelle, in the Isle of Oesel, in the Baltic. These remains consist chiefly, if not entirely, of more or less imperfect examples of the dorsal shield. Although Tremataspis has always been classified with primitive vertebrates like

Cephalaspis and Pteraspis, the curious resemblance presented by its shield to the carapace of the modern crustacean commonly known as Apus has long been recognised. This resemblance, the author contends, is not a mere accident, but indicates genetic affinity between the two groups. Accordingly, he proposes to regard Trematapsis, Pteraspis, Cephalaspis and Pterichthys as the representatives of a new class of arthropod-like animals under the title of Peltacephalata. And he urges that the genetic relationship between this group and the arthropods "can mean nothing else than the derivation, through changes in structure and function, of the one group from the other." A further proposal is to group together into one great phylum the vertebrates and the arthropods, under the name of Syncephalata. It will be interesting to note what the authors' fellow-workers have to say in regard to this startling new departure in classification.

To the April number of the *Ibis*, Mr. W. E. Clarke communicates an account of a month spent by himself last autumn on the Eddystone for the purpose of observing bird-migration. On the night of October 12 the author was fortunate enough to witness a great "rush" of emigrating birds, which continued until the early hours of the 13th. Although the majority of the migrants were British, the presence of the redwing and the fieldfare indicated a foreign contingent, and it was also noted that the starlings taken on this occasion belonged to the race characterised by the purple head and green ear-coverts, which is believed to be continental in habitat. "Throughout the movement, and especially when it was at its height in the earliest hours of the morning," writes Mr. Clarke, "the scene presented was singular in the extreme and beyond adequate description. Resplendent, as it were, in burnished gold, hosts of birds were fluttering in, or crossing at all angles, the brilliant revolving beams of light; those which simply traversed the rays were illumined for a moment only, and became mere spectres on passing into the gloom. The migrants which winged their way up the beams—and they were many—resembled balls or streaks of approaching light, and they either struck the lantern, or, being less entranced, passed out of the rays ere the fatal goal was reached. Of those striking, some fell like stones from their violent contact with the glass, while others beat violently against the windows in their wild efforts to reach the focal point of the all-fascinating light."

THE skeleton and skin of the okapi recently received at the Congo Museum, Brussels, add important information to our knowledge of that animal. The specimens have been submitted to Dr. Forsyth Major, who published a preliminary note on the results of his examination in *La Belgique Coloniale* of May 25, and also gives a figure of the male skull in the same journal of June 8. The Brussels specimens comprise the skeleton of a male, unfortunately lacking two of the vertebræ of the neck, and the skin of a female, both belonging to adults. These show that full-grown individuals of both sexes are provided with horns. Those of the female are comparatively small, conical, nearly vertical and completely covered with skin. Those of the male, on the other hand, are larger, subtriangular and inclined somewhat backwards, each being capped with a small polished epiphysis, which appears to have projected through the skin investing the rest of the horn. As regards its general characters, the skull of the okapi appears to be intermediate between that of the giraffe on the one hand and that of the extinct Palæotragus, or Samotherium, on the other. It has, for instance, a greater development of air-cells in the *diploë* than in the latter, but a much smaller one than in the former. Again, in Palæotragus the horns (present only in the male) are situated immediately over the eye-sockets, in Ocapia they are placed just behind the latter, while in Giraffa they are partly on the parietals. In general form, so far as can be judged from the disarticulated skeleton, the okapi was more like an antelope than a giraffe, the fore and hind cannon-bones, and consequently the entire limbs, being of approximately equal length. It is further suggested that, owing to the skin having been unduly stretched in drying, the neck and fore-limbs of the immature mounted specimen in the British Museum may be somewhat too long. From all this it seems probable that Palæotragus and Ocapia indicate the ancestral stock of the giraffe line; while it is further suggested that the apparently hornless Helladotherium of the Grecian Pliocene may occupy a somewhat similar position in regard to the horned Sivatherium of the Indian Siwaliks.

THE second volume of the *Minnesota Botanical Studies* is completed with the issue of the May number. Mr. Bruce Fink contributes an article dealing with the lichens of north-western Minnesota. The *Corallinae verae* of Port Renfrew, Vancouver Island, B.C., form the subject of a short systematic account by Mr. K. Yendo. The concluding paper, by Prof. Conway Macmillan, deals with the anatomical investigation of *Pterygophora californica*, one of the Laminariaceæ.

IN the first quarterly *Bulletin* for this year issued by the Botanical Department at Trinidad will be found an account of some experiments the results of which promise to be of value to cacao planters. Attempts have been made to graft cacao plants on strong stocks, in the hope that liability to the attacks of fungi may be reduced. So far, successful grafts on *Theobroma bicolor* and *Herrania albiflora* have been obtained, and trials are being made with stocks of *Cola acuminata*. Another somewhat novel experiment is in progress of treating the soil with mulchings of vegetable matter during the dry season. This serves to attract earthworms, and they act as carriers of manure to the roots of the cacao plants. Attention is also drawn to the advantages of using chupons or gormandisers on the plantations.

IN the report for last year, issued from the Royal Botanic Gardens, Ceylon, Mr. J. C. Willis, the director, gives further proof of his capability as an organiser and investigator. To aid in purely scientific work he has the assistance of four experts —a mycologist, a chemist, an entomologist and an assistant. Besides investigating the diseases of tea and cacao plants, experiments have been made with other plants which may prove to have an economic value. While so far no industry of a first-class nature has been brought to light, several minor industries which may be undertaken on existing plantations have been instituted. Hevea plants now under cultivation have yielded rubber superior to the best wild Para. Indigenous species of Palaquium were investigated by the assistant, and rubber of fair commercial value was obtained; this, too, without cutting down the tree. Camphor, citronella oil, cinchona, coca have also been brought to the notice of planters. The laboratory at Peradeniya has been well patronised by English and foreign visitors, and with the establishment of a laboratory and rooms at Hagkala facilities are offered for research in the hill country. The director has completed his review of the flora of the Maldive Islands, and has published it in the new journal, the *Annals* of the Royal Botanic Gardens, Peradeniya.

WE have received a copy of the fifth volume of the *Transactions* of the Inverness Scientific Society and Field Club. It embodies the work of four sessions, ending with the summer of 1899, but there is appended a summary of Dr. John Horne's address to the geological section of the British Association in 1901. Some time has therefore elapsed since the reading of the papers now published, which deal with history and archæology as well as natural history, physics and engineering.

There is a suggestive paper by Dr. Mackie, of Elgin, on "The Felspars present in Sedimentary Rocks as Indicators of the Conditions of Contemporaneous Climate."

MESSRS. J. J. GRIFFIN AND SONS, LTD., have issued a new edition of their illustrated catalogue of chemical apparatus and reagents published under the title "Chemical Handicraft." Hints on manipulation of instruments and arrangement of apparatus are occasionally given, and they assist in making the volume a useful catalogue for chemical laboratories and technical schools.

NEW and revised editions have been received of several well-known scientific books. The fourth edition of Prof. Grenville Cole's "Aids to Practical Geology" has been published by Messrs. C. Griffin and Co. The book is the most helpful guide which the student who desires to become intimately acquainted with the characters of rocks and minerals could possess. It is not intended to take the place of a field geology, but to show how every specimen obtained may be minutely examined in the laboratory or study, and its place among rocks or fossils understood. Work of this kind is practical geology in as scientific a sense as observations in the field.—Messrs. Cassell and Co. have published a popular edition of Mr. Richard Kearton's interesting book "With Nature and a Camera." The 180 pictures reproduced from photographs by Mr. Cherry Kearton have given pleasure to many outdoor naturalists.—The valuable text-book of "Agricultural Botany," by Prof. J. Percival, published by Messrs. Duckworth and Co. and reviewed in these columns in October, 1900 (vol. lxii. p. 570), has reached a second edition. It is satisfactory to know that students of agriculture are using a book in which plant structure and growth are dealt with scientifically.—The eighth edition of "Astronomy with an Opera Glass," by Mr. G. P. Serviss, has been published by Messrs. Hirschfeld Brothers, Ltd.—A new edition of Prof. J. G. Macgregor's "Elementary Treatise on Kinematics and Dynamics" has been published by Messrs. Macmillan and Co., Ltd. Few changes have been made, and the book retains its character as a comprehensive treatise in which the whole subject is treated systematically, without reference to the requirements of examining bodies.

THE additions to the Zoological Society's Gardens during the past week include a Dusty Ichneumon (*Herpestes pulverulentus*) from South Africa, presented by Capt. A. Perkins; two Larger Egyptian Gerbilles (*Gerbillus pyramidum*) from North Africa, presented by Col. Momber; a Buffon's Touracou (*Turacus buffoni*) from West Africa, presented by Capt. H. A. Thorne; two Long-tailed Whydah-birds (*Chera progne*) from South Africa, presented by the Rev. R. Armitage; a Richardson's Skua (*Stercorarius crepidatus*) European, presented by Lt.-Col. L. H. Irby; a Sykes's Monkey (*Cercopithecus albigularis*), a Grant's Gazelle (*Gazella granti*), a Banded Ichneumon (*Crossarchus fasciatus*), a Vulturine Guinea Fowl (*Acryllium vulturinum*), a Bateleur Eagle (*Helotarsus ecaudatus*), three White-winged Whydah-birds (*Urobrachya albonotata*) from East Africa, a Buffon's Touracou (*Turacus buffoni*), a Red-faced Weaver-bird (*Foudia erythrops*), seven Orange Weaver-birds (*Euplectes franciscana*), two Pintailed Whydah-birds (*Vidua principalis*), three Paradise Whydah-birds (*Vidua paradisea*) from West Africa, two Maguari Storks (*Dissura maguari*), two Snowy Egrets (*Ardea candidissima*), four Black-pointed Teguexins (*Tupinambis nigropunctatus*), four South American Rat Snakes (*Spilotes pullatus*) from South America, two Brazilian Cariamas (*Cariama cristata*) from Brazil, deposited; a Black-winged Peafowl (*Pavo nigripennis*) from Cochin China, purchased; a Great Bird of Paradise (*Paradisea apoda*) from the Arrow Islands, received in exchange; a Brindled Gnu (*Connochaetes taurina*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE SUNSPOT CURVE AND EPOCHS.—The great importance of collecting as many facts as possible regarding solar activity, and revising them from time to time as new information is gathered, is clearly shown by the paramount *rôle* that the sun plays in causing the numerous variations in meteorological phenomena. Wolf's relative numbers have been, and are now, so commonly used when reference has to be made to solar activity that it is of the first importance that such a series of values should be as near correct as possible. It is with great satisfaction, therefore, that we note that Wolfer has so diligently continued the useful work, ably begun by Wolf, that he has now published (*Meteorologische Zeitschrift*, May, 1902) a new set of values carefully revised and brought up to date. As he remarks, an examination of the original manuscript at the observatory with various published tables has shown that a great number of differences and printer's errors have crept in, suggesting that it is time that a new edition was published. This reduction has been very carefully made by Wolfer and his assistant, each making the computations twice. In addition to the observed relative numbers, the paper gives smoothed relative numbers, while a third table shows the epochs of maxima and minima with their corresponding weights; the addition of the weights to the dates of these epochs is a very valuable piece of information which will add to the utility of the earlier epochs.

METHOD OF OBSERVING ALTITUDES AT SEA DURING NIGHT-TIME.—In a paper read before the Royal Dublin Society, Prof. Joly introduced recently a method for observing the altitude of a celestial body at sea which may prove extremely useful for taking bearings at night-time or when the horizon is obscured. Assuming that the vessel is provided with the usual Board of Trade rescue signals, one of these is perforated and dropped overboard. This will furnish a bright white light visible in clear weather up to five miles, and burning for about half an hour. To the signal is attached a suitable sinker, so that it will not drift appreciably. Selecting a star, the observer takes its bearing and then alters his course to the opposite bearing, thus bringing the star right astern. The signal is then dropped overboard, and at the same time a reading of the log is taken. After the vessel has travelled a distance of about a mile from the signal, as indicated by the log, the observer takes the angular elevation of the star over the signal, using the sextant in the usual manner. Corrections will have to be applied for the relative motion of the star from east to west at the rate of 1° in four minutes of time, for the larger angle of "dip," and also for the state of the water surface. In very rough water this last correction becomes of special importance, and formulæ with reduction tables are given to show the influence of waves of varying heights. The routine to be followed in observing two altitudes for a "Sumner" position is also described (*Scientific Proceedings* of the Royal Dublin Society, vol. ix., n.s., part v., No. 46, pp. 559–567).

LIQUID FUEL FOR STEAM PURPOSES.

THE possibility of burning a liquid fuel with very great advantage in most circumstances as compared with a solid fuel has been so long recognised that it is astonishing the practice has not been more generally adopted. The success which has been gained in the last few years, however, will undoubtedly lead to a greatly extended use in the near future.

Naturally the choice of a fuel for steam raising is not altogether dependent upon the evaporative efficiency and other advantages which a particular one may possess, but will, of course, be largely influenced by relative market prices, and this, no doubt, has had considerable influence against the adoption of liquid fuel on a large scale in this country. The fuel natural to the locality will always have great advantages over an imported fuel, and England, having such valuable coal supplies to hand, whilst on the other hand having no great natural sources of liquid fuel, gives preference to that material which renders it most independent of outside supplies. Although gas tar and oil gas refuse may be frequently employed in a very economical manner, yet there is little doubt that with a greatly extended use of liquid fuel the prices of suitable bye-products would be so enhanced that imported liquid fuel would remain practically in possession of the field.

For this reason engineers who have perfected the methods of

burning liquid fuel have always considered the possibility of its use becoming limited in certain circumstances, and all modern appliances are so constructed that with slight trouble coal alone may be used in them to the best advantage. One of the great claims to be considered in favour of liquid fuel is the ease with which the burners can be extinguished and a coal fire substituted, thus enabling consumers to take every advantage of fluctuations in the prices of both fuels. For marine purposes this is most desirable, since at many ports liquid fuel would be far more economical to ship for boiler use than a suitable steam coal, whilst a vessel trading from a port—such as Cardiff or Newport—would naturally replenish her bunkers with the steam coal at hand.

Any liquid hydrocarbon of sufficiently high flash point may be used as a liquid fuel; thus residues from many manufacturing processes may be utilised in an economical manner. Astatki, the residuum from petroleum distillation, has been extensively used in Eastern Europe, but tar oils and the oils from oil gas plant are frequently employed. These oils are especially suitable for locomotive work, since most large railways make oil gas in considerable quantities for lighting purposes, and, moreover, have exceptional facilities for transporting gas tar from small towns on their lines where it can be obtained at a reasonable cost. On the Great Eastern Railway this form of liquid fuel is largely employed. Crude petroleum, which has been treated to remove the more volatile constituents and so bring its flash point above the imposed limit for use as fuel, is now being imported into this country. The various methods of burning liquid fuel have been classified by Aydon as follows:—

(1) *Injection with compressed air* (W. Bridges Adams, 1863; Tarbutt, 1885.)

(2) *Percolation through a porous bed* (C. J. Richardson, 1864; Weir and Gray; St. Caire Deville), in which the liquid fuel percolates upwards through a porous bed, accompanied by heated air (and sometimes steam also).

(3) *Vaporisation* (Foote; Simm and Barff, 1865-67), the oil being vaporised from a small retort heated in the furnace, or in some cases (Dorsett, 1868-69; Eames, 1875) by a special external heater for the retort.

(4) *Steam spray injection* (Aydon, Wise and Field, 1865-67), in which the oil is sprayed into the combustion chamber by a jet of steam, whilst at the same time the burner is so constructed that air, heated if possible, is drawn in to supply the oxygen necessary for combustion.

Such a classification does not include burning in open troughs, a method first introduced by Wittenström about the year 1884, and which for many purposes in stationary boilers, furnaces, &c., has met with considerable success; or the more recent method of Korting, by direct injection of heated oil at considerable pressure.

Excepting in a few special cases, the steam spray injection method has been universally adopted. Various extravagant claims have been made for the chemical action of the steam, but it is not easy to see from a theoretical standpoint that it has any advantage over injection by compressed air. From a practical point of view, however, the steam spray is the more simple, since it dispenses with the auxiliary apparatus necessary for the supply of the air blast. On a locomotive, where economy of space is of importance and suitable water for the boilers is readily obtainable, steam spray injection is universal. For marine boilers the choice formerly lay between steam and air injection, each having certain advantages. Using steam injection, the auxiliary apparatus necessary for the air-blast is done away with, thus giving economy of space, whilst it has the disadvantage of requiring more condensed water from the evaporators to replace the steam used. On the other hand, the extra steam necessary for the air-blowers can be condensed and returned in the usual way to the feed water-pipe, but of necessity extra machinery has to be employed. With the introduction of the Korting system referred to above, and the success which has attended its use, notably on the Hamburg-American Line steamers, the marine engineer now has the choice of another method, and everything seems favourable to the extensive adoption of this new system in the future.

From the numerous estimations of the calorific value of different liquid fuels, we may approximately state that in centigrade units it has a value of 10,500, whilst for good steam coal a value of 8000 to 8500 may be taken. It will thus be seen that the liquid fuel has a decided advantage. The usual calculations of the theoretical heating value of a fuel fail to take one important factor into consideration, namely, the physical condition of the fuel. Thus the determined calorific value of carbon is always that of solid carbon, the value for hydrogen being obtained experimentally for hydrogen gas; but although in coal the carbon is in the solid form, it is certain that in liquid fuels it has undergone the first change in the passage of a solid to a gaseous condition, and consequently carbon in a liquid fuel will have a higher calorific value by just as much heat as would be required theoretically to raise solid carbon to the liquid condition. Aydon has estimated that this is equivalent to an expenditure of some 3500 calories.

It is, of course, impossible even with the most perfect appliances to obtain anything like the full heating effect of a fuel in any boiler, and the only real test of the value of competing fuels is their performance under similar conditions in practice. One is struck at the outset with the extremely contradictory figures which have been published to show the evaporative duty of liquid fuel, figures ranging from 46 lbs. of water per lb. of fuel burnt to 14 or 16 lbs. per lb. It may be taken, however, that in modern practice an efficiency of 15 lbs. by steam injection is a very fair result. Many comparisons have been made with coal in the same boilers and under the same conditions with results varying from 7 to 8½ lbs. of water evaporated per lb. of coal consumed. A valuable series of tests made by the Engineers' Club of Philadelphia in 1892 gave the following results:—

1 lb. anthracite evaporated	9·7 lbs.	of water.
1 lb. bituminous coal	10·14 ,,	,,
1 lb. oil 36° B.	16·48 ,,	,,
1 cu. ft. of gas 20 C.P.	1·28 ,,	,,

We are indebted to the carefully recorded results obtained by Mr. Urquhart on the Grazi and Tzaritzin Railway for probably the best published figures of the relative merits of solid and liquid fuels. In winter he found that liquid fuel was 41 per cent. in weight and 55 per cent. in cost better than anthracite coal; or, compared with bituminous coal, 49 per cent. by weight and 61 per cent. in cost better. This was under the worst climatic conditions, and, as might be expected, in summer better results still were obtained. It must be borne in mind that these figures were deduced from the work of a large number of engines.

The Canadian Pacific Railway find that liquid fuel in use on their steamers effects a saving of 56 per cent. on the cost of coal firing.

In this country the pioneer of liquid fuel on our railways is Mr. James Holden and his company; the Great Eastern Railway has now more than sixty engines burning it, either alone or in conjunction with coal. In a note presented at the International Railway Congress in 1900, Mr. Holden gives the following particulars of express trains running between Liverpool Street and Cromer. The distance of 138 miles is covered in 175 minutes with a four minutes' stop, on a consumption of 14·4 lbs. of tar residues per train mile, and an equivalent of 5 lbs. per mile of coal, which is used in raising the steam necessary for starting the oil injectors. In the same paper it is stated that on railways working with wood fuel a saving of 50 per cent. has been effected by burning liquid fuel. Through the kindness of Mr. Holden, the writer recently made a long run on an engine burning crude coal tar over a coal fire with the Holden steam injectors, and was impressed with the ease of maintaining a regular steam pressure and the freedom from smoke.

The South Eastern and other railways are now fitting engines for this class of fuel, and an oil-fired engine is used for shunting on the Central London Railway. Boilers are also being fitted for liquid fuel at Woolwich Arsenal, and its use is extending amongst private firms.

In the English shipping trade the pioneers have been Messrs. Samuel and Co., the managers of the Shell Transport Company, and a reference to the excellent performance of their vessel the s.s. *Clam* will be found in a recent number of NATURE. An interesting account of the record voyage under liquid fuel appears in the *Shipping Gazette* of February 13, the vessel being the s.s. *Murex*, also belonging to the Shell Transport Company. This ship arrived at Thames Haven from Borneo *viâ* Singapore and the Cape on March 10, having steamed 11,830 miles on a consumption of 800 tons of prepared fuel.

The average daily consumption was from 17 to $18\frac{1}{2}$ tons, whilst the same vessel when under coal used from 24 to 25 tons.

The economy of cost in liquid fuel does not lie entirely in its superior evaporative value, for several other factors are all in its favour, and probably the greatest of these in the marine service is the reduction in the stokehold staff. Potter states that with fourteen tubular boilers (16 feet × 5 feet) twenty-five men were required for stoking with coal, but on the introduction of liquid fuel six men sufficed. On the s.s. *Murex*, referred to above, whilst more than twenty stokers were required when under coal fires, only three were carried to attend the oil burners. When the cost of wages, food, &c., for the large number of stokers carried on an average liner are taken into consideration, the possibilities for economy by the adoption of liquid fuel, when it can be obtained at a reasonable price, are very great. In the Royal Navy, where the stokers carried on a battleship run into big numbers, not only does liquid fuel tend to economy, but an even more important factor—the number of lives risked in an engagement—would be largely reduced. It is terrible to contemplate the fate of the engine-room staff in the event of one of our big ironclads being sunk by a torpedo or the ram of an adversary's ship.

For storage, liquid fuel has a slight advantage over coal. In general terms it may be said that one ton of liquid fuel will require 36 cubic feet of storage and steam coal from 43 to 45 cubic feet; but it must be remembered that coal bunkers have of necessity to be specially arranged for the easy delivery of the fuel at the stokehold level, whereas liquid fuel may be carried in places where the storage of a solid fuel is quite out of the question. By the adoption of some system of removing water from the oil, such as that of Flannery and Boyd, where two settling tanks are alternately employed, liquid fuel may be stored in water-ballast tanks and the fore and aft peaks of the vessel. Remembering that one ton of oil fuel has such a much larger evaporative efficiency than the same weight of coal, and, further, has advantages in storage, a very much larger cargo space can be reserved in a vessel, or in the case of the belligerent marine, with no greater total weight of fuel on board, a very greatly extended radius of action can be obtained.

A point in connection with coal as a fuel in steamships which is often overlooked is the large amount of inert material which must necessarily be carried in the bunkers; for example, a ship takes into her bunkers 2000 tons of steam coal (H.M.S. *Queen*, which was recently launched, has a coal capacity of 2040 tons), and taking a fair estimate of the ash of this coal at 5 per cent., it means finding space for at least one hundred tons of non-usable mineral matter, even assuming that the ash and clinker do not exceed the ash of the coal. In the case of liquid fuel, the whole amount stored is actually available as fuel, and there is no trouble with ash or clinker in the furnaces, or solid waste of any description to be got rid of.

On any vessel, and especially on a ship carrying passengers, the operation of coaling is a particularly disagreeable one. With liquid fuel there is really no inconvenience, for the oil can be pumped into the tanks in much less time than coal shipment takes, and, further, all the dirt associated with "bunkering" is avoided. At the present time it is well known that the Admiralty is carrying out experiments in coaling war vessels at sea, the collier being made fast astern and the coal hauled along a suitable transport arrangement. It would undoubtedly be a much simpler operation to transfer liquid fuel through a flexible hose of slightly greater length than the cables made fast between the two vessels, providing that an oil of reasonable viscosity was employed.

Even in a country possessing such splendid supplies of steam coal as England, liquid fuel is now making rapid headway, and this is not surprising when one considers the high prices reached for coal of all descriptions during the last two or three years. To be able to fall back on liquid fuel, when it can be obtained at a reasonable price, places the consumer in an independent position as regards the colliery proprietor, and the necessary fittings to enable this to be done are by no means costly. Coal at a fair price will probably always have the advantage over imported liquid fuel, but in countries entirely dependent upon mported fuel, the liquid form must in the future be the main upply, for bulk for bulk it is twice as efficient as any solid fuel, nd, moreover, its transport in suitable vessels is attended with far less risk than with coal cargoes shipped from a great distance.

J. S. S. BRAME.

THE MURCHISON FALLS.

THE new Government road from the capital of Uganda to Butiaba on the Albert Nyanza will shortly cause the existing caravan track, which crosses the Nile at Fajao, to be abandoned. The latter place obtained some notoriety during the Uganda mutiny 1897-8, but, not being exactly a health resort, the station was soon after given up, and a few Sudanese of the Uganda Rifles now guard the ferry.

On an isolated mass of rock overlooking the Nile, the European quarters are (or were when I passed through on my way from East Africa to the Sudan in October last) still marked by a couple of thatched huts in dilapidated condition, a flower-garden, and a flag-staff from which fluttered the remains of a "Union Jack." From the station a beautiful view of the Murchison Falls, about a mile distant, can be obtained.

Close to the station are two more isolated masses of biotite gneiss, and undoubtedly the river, which is here confined in a deep cañon, has carved its way eastward for one-and-a-half miles to the present falls, leaving these masses as "witnesses."

On arrival, I was struck by the peculiarly irregular sound of the falls; at night it is especially noticeable.

The track to the falls, used by native fishers, at the foot of the cliffs on the south side, follows close to the water's edge, and the sight of five crocodiles with wide-opened mouths on the opposite shore suggested unpleasant possibilities. Usually crocodiles can be seen in hundreds.

Scrambling along the slippery track, much overgrown in places, and glittering with disintegrated mica flakes, we passed several naked Wanyoro fishers in their canoes, and the decaying remains of fish, chiefly a species of perch, showed their favourite landing places.

Arriving at the 200-foot basin into which the fall takes its final plunge, one notices how the constant spray from the falls, ascending in clouds like steam, allows the luxuriant vegetation to grow over even the vertical cliffs surrounding the basin on three sides, except where the soft mica schist has caved in by weathering. A double rainbow added to the beauty of the scene, but the near view of the falls is distinctly disappointing.

The peculiar intermittent roar could now be accounted for; a mass of water tumbling headlong into the pool is immediately followed by an enormous broken wave, then comes a lull, and the process is repeated.

As this phenomenon was inexplicable from below, I suggested that a climb to the top of the falls was advisable; and after much discussion our Nubi guide extracted from an airily clad Mnyoro the information that a track did exist to the top of the south cliff. It proved to be a most trying 200-foot climb up a steep slope covered with dense grass, and it could only have been made by an energetic European. A short downward scramble led to a rock plateau with potholes, the largest of which was 15 feet in diameter and 10 feet deep, filled with water, marking the level of the former bed of the river when it swirled round a mass of gneiss in its centre. This being gradually worn away on the south side, apparently exposed a softer vein, and the river has cut its way through, in a deep vertical cleft from 20 to 30 feet wide and of unknown depth. A well-known officer in the Uganda Rifles whom I met two days later informed me that he had measured the narrowest portion accessible and found it only 18 feet wide.

Now the Nile above this is a succession of falls, and, after a sharp bend to the north-west, turns again west when 200 feet wide and, gradually narrowing, tumbles 10 feet over a rock ridge spanning the river and then over a 5-foot ridge. For 50 feet it rushes with increasing velocity and finally enters the extraordinary cleft. Down this, for 150 feet, the river "slithers," a solid mass of water, as if through a sluice. Suddenly it meets with an obstruction, a harder layer of gneiss through which it is undercutting its way, and with terrific force strikes this, and rebounds, sometimes with a huge shower of spray. Meanwhile the body of water behind has to find an outlet, and, still confined between high walls, is forced over the ridge with irresistible force ere, 250 feet further on, it tumbles over the last fall into the large basin below, and the back wave, now a vast boiling mass, follows hard after it. This explains the peculiar sound of this fall.

The pent-up power of the Nile as it leaps the barrier is extremely impressive, but from an engineering point of view it is regrettable that such enormous power is running to waste.

I returned to Fajao at sunset, in time to see the Nile tinged a

rich crimson as the sun sank behind the lofty range of mountains west of the Albert Nyanza, and, contrasted with the deep green foliage of the river banks, the scene was striking. But by far the most superb sight was the fall itself under the light of a full moon that night. For the identification of the rock specimens from the falls, consisting of biotite gneiss, mica schist, garnetiferous mica schist, and quartz, I have to thank Mr. G. T. Prior, of the Natural History Section of the British Museum. C. Steuart Betton.

THE MANUFACTURE AND USES OF SODIUM.

The manufacture and uses of metallic sodium is the subject of an interesting article by Mr. James D. Darling in the January number of the *Journal* of the Franklin Institute, from which we take the following facts.

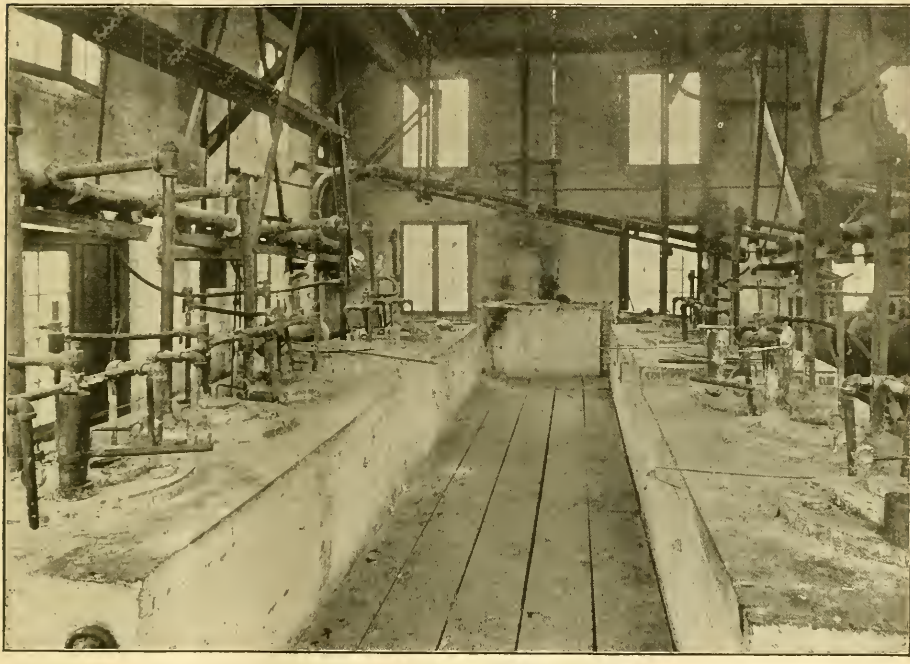

Fig. 1.—General View of Sodium Furnaces.

From the time of its isolation in 1801 until 1858, the cost of sodium was exceedingly high. In 1858, Deville perfected the process of manufacture by heating sodium carbonate, chalk and coal in an iron retort and condensing the sodium vapour thus produced. The price then fell from 2000 francs to 10 francs per kilo. No further important advance in the manufacture was made until the late Mr. Castner took up the subject, and after using with great advantage a modification of Deville's process in which carbon was replaced by a compound of carbon and iron and carbonate of soda by caustic soda, he succeeded in 1890 in making Davy's original method available on the large scale, that is to say, the method of decomposing fused caustic soda by the electric current. Most of the sodium used to-day is made by this process.

Attempts to make sodium from its cheapest compound, the chloride, have so far been unsuccessful, owing chiefly to the high melting point (800° C.) of the chloride and to its corrosive action when in the molten state.

The process introduced by Mr. Darling involves the electrolysis of sodium nitrate with the liberation of sodium and of nitrogen peroxide, which is then converted into nitric acid.

The decomposition cell consists of a cast-iron pot set in a brick furnace. At the bottom of the pot is a 6-inch layer of refractory insulating material, and on this rests a cup 30 inches high, 16 inches outside diameter, with walls 4 inches thick. This cup is made of two sheets of perforated steel, between which is a mixture of ground deadburned magnesite and Portland cement which has been mixed with water and allowed to set hard. The space between the cup and the pot is filled with sodium nitrate (M.P. 313° C.) and the cup itself with melted caustic soda (M.P. 320° C.). The cast-iron pot acts as the anode, and 5 per cent. of the current is advantageously shunted through the metal walls of the cup. The kathode consists of a short length of 4-inch wrought-iron pipe reaching nearly to the bottom of the cup. Each furnace takes a current of about 400 ampères at an average E.M.F. of 15 volts, and external heat is used only when starting up or when changing the cups, which have a life of 425 to 450 hours. When the current is passed, nitrogen peroxide and oxygen are liberated at the anode and escape through a hole in the cover of the pot. Sodium is liberated at the kathode, and rises to the top of the cup, where at intervals of an hour it is dipped off with a spoon and preserved under mineral oil.

The aim of this new process is to decompose sodium nitrate in such a way that the sodium is liberated in a medium which will not oxidise it, and to get the nitrogen peroxide for the manufacture of nitric acid. How this is done will be evident from the description just given; the sodium ions of the fused nitrate travel through the walls of the porous cup to the fused caustic soda; they act upon the caustic soda until it is converted

(probably) into the monoxide, hydrogen being liberated, and when this is once achieved the following sodium ions form metallic sodium at the kathode. The use of two electrolytes with a common cation enables the sodium to be liberated in such a way as to escape oxidation by the fused nitrate. It is obvious that the only substance used up is the nitrate. Fig. 1 gives a general view of the sodium furnaces.

The nitrogen peroxide and oxygen evolved at the anode are conducted by earthenware pipes to a number of Woulff's bottles, connected together and containing water. The arrangement is shown in Fig. 2. The action of NO_2 on water is as follows:— $3NO_2 + H_2O = 2HNO_3 + NO$. The NO takes up more oxygen to form NO_2 and more nitric acid is produced. If very strong acid is required, a system of absorbing towers is used.

Sodium is now used on the large scale for making sodium peroxide and sodium cyanide. The peroxide is made by burning sodium in an excess of dry air free from CO_2 in an externally heated retort. It is a valuable oxidising and bleaching agent, replacing the most costly hydrogen peroxide.

Sodium is used in making cyanides by Erlenmeyer's process, in which the metal is heated wirh potassium ferrocyanide, $K_4FeC_6N_6 + 2Na = 4KCN + 2NaCN + Fe$. Potassium carbonate is usually added so as to make the percentage of CN in the mixture equivalent to that of pure KCN.

Another method of using sodium in the manufacture of cyanides is to make sodamide by heating the metal in ammonia gas, $Na + NH_3 = NaNH_2 + H$. The sodamide may then be heated with carbon, $NaNH_2 + C = NaCN + H_2$. or, according to another process, it may be made to first form a cyanamide, $2NaNH_2 + C = Na_2N_2C + 2H_2$. The cyanamide is then treated with more carbon at a higher temperature, $Na_2N_2C + C = 2NaCN$.

Mr. Darling states that he has devised a new method of preparing cyanides in which he avoids using so much sodium in the metallic state.

FIG. 2—Apparatus for converting Nitric Oxide into Nitric Acid.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Considerable changes will be introduced into the examination for Mathematical Honours, Moderations, by a scheme which comes into effect in 1904. The main features of this scheme are (1) the legalising of the use of the infinitesimal calculus in answering questions on mechanics; (2) the abolition of restrictions on the freedom of choice of method, analytical or synthetic, in the treatment of geometry; (3) the introduction of the elements of analytical solid geometry.

CAMBRIDGE.—The following are the speeches delivered by the Public Orator, Dr. Sandys, on June 10, in presenting for the degree of Doctor in Science *honoris causa* (1) Sir Harry Hamilton Johnston, G.C.M.G., K.C.B, Special Commissioner for the Uganda Protectorate, and (2) Dr. A. W. Rücker, F.R.S., Principal of the University of London:—

"Semper aliquid novi Africam adferre" etiam inter antiquos dicebatur. In Africa nuper ab hoc viro, ne plura commemorem, camelopardalis speciem novam repertam esse constat. Idem Africae in regione septentrionali, occidentali, orientali, Africa etiam in media, patriae personam summa cum dignitate gessit; Africae montes, flumina, lacus exploravit; exploratos et pingendi et scribendi arte eximia ante oculos nostros posuit. Quid dicam de libris illis, quorum in uno Livingstonii vitam egregie narravit; in alio colonias omnes ab Europae gentibus in Africam deductas luculenter descripsit; in alio denique Afrorum

servitutis imaginem vividam expressit? Talium virorum laboribus indies plura de Africae regione immensa cognovimus, et telluris illius tenebras luce indies maiore illustratas cernimus. Duco ad vos virum a societate zoologica numismate aureo honoris causa donatum, equitem insignem, HARRY HAMILTON JOHNSTON.

Universitatis Londiniensis nuper denuo constitutae praesidem primum ea qua par est observantia salutamus, virum studiis mathematicis olim excultum, Collegii sui inter Oxonienses honoris causa socium; primum in comitatu Eboracensi, deinde inter Londinienses scientiae physicae professorem; Societatis Britannicae scientiarum finibus proferendis nuper praepositum; Regiae denique Societatis inter lumina iamdudum numeratum. Qui insulae Britannicae explorationem magneticam non semel tantum ad finem felicem perduxit, nunc Universitati maximae est praepositus, in qua, animi vi quadam magnetica praeditus, collegarum suorum omnium corda ad se attrahit, et Universitatis totius ad communem fructum Londiniensium liberalitatem allicit. Duco ad vos Universitatis Londiniensis praesidem insignem, ARTHURUM WILLELMUM RÜCKER.

HOLIDAY courses in botany, physics, physiology and zoology will be held at the University of Jena from August 4 to August 16. Particulars and detailed programmes of these and other courses can be obtained from the secretary, Mrs. Dr. Schnetger, 2 Gartenstrasse, Jena.

THE discussion of the Education Bill was resumed in Committee of the House of Commons on Tuesday. An amendment providing that the council of a borough with a population of more than 10,000, or an urban district with a population of more than 20,000, must obtain the consent of the council of the county in order to become the local authority for elementary education was put to the vote and negatived. A proposal to omit the whole of the clause which constitutes the county councils local education authorities was also rejected.

AT a meeting of the council of the Institution of Mining and Metallurgy on Tuesday, it was decided to offer scholarships in mining and metallurgy to the following colleges:—The Royal School of Mines, two scholarships of 50*l*. each; King's College (London), 50*l*.; the Camborne School of Mines (Cornwall), 50*l*.; and the Durham College of Science (Newcastle-on-Tyne), 50*l*. These scholarships will be offered annually for three years. In addition to other work for the advancement of technical education in mining and metallurgy, the Institution has submitted to the Board of Education a comprehensive scheme for affording practical experience in workshops throughout the kingdom to mining and metallurgical students, and it is expected shortly to be put in force.

AT a special meeting of the council of King's College, London, held on Friday last, it was resolved by twenty-two votes to two, "That, in view of the situation created by the University of London Act, 1898, the council, while determined to maintain the connection of the college with the Church of England as set forth in section 5 of King's College, London, Act, 1882, resolves that, so soon as may be, every religious test as a qualification for office, position, or membership in or under the council or college, other than professorships or lectureships in the Faculty of Theology, shall cease to exist, and, further, that all necessary and proper steps be taken to give effect to this resolution." The section referred to in this resolution specifies the following as the purpose of the college:—To give "instruction in the various branches of literature and science and the doctrines and duties of Christianity as the same are inculcated by the Church of England."

A SUCCESSFUL exhibition, designed to show the provision made for science teaching in the secondary and elementary schools of Hampshire and the Isle of Wight, was held at the Hartley College, Southampton, on Saturday last. A well-arranged series of exhibits enabled the visitor to see at a glance the encouragement given by His Majesty's inspectors and others to the construction of simple home-made apparatus to illustrate the principles of physics and chemistry. It was clear from the work of students which was on view that considerable prominence is being given to nature study in these districts; and the collections and drawings of biological subjects of the kind shown should serve to extend and improve the teaching of botany and zoology in schools. The conference of teachers held at the Hartley College in connection with the exhibition, to discuss methods of teaching science, was largely attended and gave evidence of a widespread desire to introduce observational and experimental methods in all scientific instruction.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, May 28.—Prof. Meldola, F.R.S., vice-president, in the chair.—Taxine, the alkaloid of yew, by Dr. Thorpe, C.B., F.R.S., and Mr. G. Stubbs. The authors have confirmed the observations of Hilger and Brande, Marmé and others on the occurrence of an amorphous alkaloid in yew.—The sampling of soils, by Dr. J. W. Leather. Comparative experiments were made in India to determine the possible accuracy of the auger method of sampling soils, the available phosphoric acid and potash being taken as a standard of comparison. The results showed that in most cases the agreement was good between the samples, but that there was occasionally a divergence of about five per cent.—Some excessively saline Indian well waters, by Dr. J. W. Leather. An examination of some well waters collected in the Muttra district, United Provinces, India, showed that they contained from ·2 to 2 per cent. of saline substances consisting of sulphate, nitrate, chloride and carbonate of sodium.—Nitrobromo-derivatives of fluorescein, by Dr. Hewitt and Mr. Woodforde. Several of these substances have been isolated and characterised.—Phosphorus sesquisulphide and its behaviour with Mitscherlich's test, by Mr. F. G. Clayton. Analyses of commercial specimens of this substance have been made, and show that they contain from 83 to 97 per cent. of sesquisulphide.—Atomic and molecular heats of fusion, by Mr. P. W. Robertson. The author finds that for a number of the elements and their binary inorganic derivatives a relation between (atomic or molecular) heat of fusion, absolute melting point and atomic volume exists which is capable of a more or less general representation by an equation of the form $Aw/T^3\sqrt{V} = \kappa$.—The preparation of mixed ketones by heating mixed calcium salts of organic acids, by Mr. E. B. Ludlam. An extension of the method proposed by Young in 1891.—Isomeric additive products of methyl, ethyl and propyl benzyl ketones with benzylidene aniline, part iv., by Dr. Francis and Mr. Ludlam.—The influence of solvents on the rotation of optically active compounds, part iii., influence of benzene, toluene, *o*-xylene, *m*-xylene, *p*-xylene and mesitylene on the rotation of ethyl tartrate, by Dr. T. S. Patterson. The above solvents exert in the order named an increasing influence in diminishing the rotation of ethyl tartrate; in the case of the first four solvents this effect reaches a minimum and a maximum at appropriate concentrations.—iv. Influence of naphthalene on the rotation of ethyl tartrate, by Dr. T. S. Patterson. The effect of this hydrocarbon is to increase the observed rotation.

Geological Society, May 28.—Prof. Charles Lapworth, F.R.S., president, in the chair.—The Red Sandstone-Rocks of Peel (Isle of Man), by Prof. W. Boyd Dawkins, F.R.S. The Red Sandstone series, ranging along the coast from Peel to Will's Strand, is faulted into the Ordovician massif of the Isle of Man. It has been referred to the Old Red Sandstone, the Calciferous Sandstone, the basement Carboniferous, and to the Permian. The series consists of red sandstones containing irregular conglomerates and breccias, more or less chemically altered, known in the lake district as "Brockram." Sections at Ballagnane, Creg Malin, and at the Gob and Traie Fogog, are described in detail; the rocks are classified, and their range to the north-east and inland is described. It is pointed out that the rocks are different in many respects from the basement Carboniferous rocks of Langness and elsewhere, and a list of the materials contained in the "Brockrams" is given. The fossiliferous pebbles in the rocks in question are described, and their fossil contents determined. The whole group of fossils is Lower Carboniferous and Ordovician, and centres mainly in the Carboniferous Limestone. A comparison is instituted with the Permian rocks of Barrowmouth, the Vale of Eden and elsewhere.—The Carboniferous, Permian and Triassic rocks under the glacial drift in the north of the Isle of Man, by Prof. W. Boyd Dawkins, F.R.S.—Note on a preliminary examination of the ash that fell on Barbados, after the eruption at St. Vincent (West Indies), by Dr. J. S. Flett, with an analysis of the dust by Dr. William Pollard (see p. 130).

Paris.

Academy of Sciences, June 9.—M. Bouquet de la Grye in the chair.—Remarks by M. Hatt on the tidal constants for a certain number of ports in France, the Indian Ocean and China.—A discussion of the magnetic observations made in the central region of Madagascar, by M. P. Colin. A striking anomaly exists at Tsiafajavona, the highest summit of the Ankaratra chain. By reason of its mass and magnitude, this chain exerts a considerable influence in its neighbourhood. A second less-marked centre of disturbance appears in the neighbourhood of Vontovorona. The eastern plateau possesses a more regular magnetic field than the western, the volcanic zones having only a local action of small radius.—On the diabetogenic leucomaines, by MM. R. Lépine and Boulud.—M. Amagat was elected a member in the section of physics in the place of the late M. Cornu.—M. Albert Gaudry announced that M. André Tournouër, who was in charge of the Patagonian expedition, had discovered important remains of Pyrotherium near Rio Deseado. The deposits containing these remains also yielded a large number of fossils of mammalia of great interest.—On functions of infinite species, by M. Emile Borel.—On a remarkable case of rational transformation in space, by M. D. Gravé. On internal combustion motors, by M. L. Lecornu.—On the electric force due to the variation of magnets, by M. E. Carvallo. A discussion of an experiment of M. Cremieu which led to results apparently in contradiction to Maxwell's theory. It is shown that this results from the manner in which M. Cremieu has applied the definition of electric force, and that the results are in complete accord with Maxwell's theory.—On the variations of the zodiacal light, by M. L. Décombe.—The accidental double refraction of liquids mechanically deformed, by M. G. de Metz. A careful study of this property for a considerable number of solutions shows that there is no necessary connection, as has usually been supposed, between the double refraction produced and the viscosity. For certain liquids the optical phenomenon lasted several seconds after the mechanical strain; the effect was especially noticeable with copal and dammar varnish and with collodion.—On a new isomerism in asymmetric nitrogen, by M. E. Wedekind. The presence of two atoms of asymmetric nitrogen in a molecule appears to render possible the existence of stereoisomeric ammonium salts.—On benzene-azobenzoic aldehyde, by M. P. Freundler. Compounds of the type $C_6H_5.N:N.C_6H_4.CO.R$ cannot be obtained by the reaction of Friedel and Crafts, but can be readily prepared by the simultaneous reduction of a mixture of nitro-compounds; thus a mixture of nitrobenzene and nitrobenzoic aldehyde reduced in this way gives benzene-azobenzoic aldehyde, the preparation and properties of which are described.—The oxidation of morphine by the juice of *Russula delica*, by M. J. Bougault. The oxydase present in the plant juice gives the same oxymorphine as is obtained by the oxidation of morphine with potassium ferricyanide.—On the lipase of the blood, by M. Hanriot. The author admits the truth of some criticisms of his former work on this subject by MM. Doyon and Morel, but holds that these experiments furnish no conclusive arguments against the existence of lipase in the blood.—On caryophysema in Euglena, by M. P. A. Dangeard.—On a permanent action which tends to provoke a negative tension in the woody vessels, by M. H. Devaux.—The volcanic rocks of Martinique, by M. A. Lacroix.—The production of a polyvalent preventive serum against pasteurelloses, by MM. Lignières and Spitz.—On the presence of a rennet in plants, by M. Maurice Javillier. The rennet obtained from the juice of rye-grass possesses all the properties of animal rennet. The ferment is met with in many different plants, ten being enumerated in the present paper.—On a qualitative difference between the excito-motor effects of open and closed induced currents, by Mlle. I. Ioteyko.—On the yeasts used for the fermentation of cider, by M. Henri Alliot.—On the bouquet of wines obtained by the fermentation of sterile musts from grapes, by M. A. Rosenstiehl. The conclusion is drawn that the quality of a wine of well-known vintage depends less upon the quality of the grape than upon the nature of the yeast which grows spontaneously upon the grape.—The action of sulphurous acid upon oxydase and on the colouring matter of red wine, by M. A. Bouffard. The protective action of the sulphurous acid acts in two ways; it has a distinctly destructive effect upon the oxydase, and also forms an unstable compound with the colouring matter which protects it from the oxygen of the air.—On the phosphates of the soil which are soluble in water, by M. Th. Schlœsing, fils.—On a new form of collecting bottle for sea-water at great depths, by M. Jules Richard.

DIARY OF SOCIETIES.

THURSDAY, June 19.

Royal Society, at 4.30.—On the Correlation between the Barometric Height at Stations on the Eastern Side of the Atlantic: Miss F. E. Cave-Browne-Cave and Prof. K. Pearson, F.R.S.—Note on the Effect of Mercury Vapour on the Spectrum of Helium: Prof. J. Norman Collie, F.R.S.—The Seed-Fungus of *Lolium temulentum*, L., the Darnel or Poisonous Rye-Grass: E. M. Freeman.—On Methods for the Limitation and Regulation of Chloroform when administered as an Anæsthetic: A. Vernon Harcourt, F.R.S.—On the Measurement of Temperature. Part I. On the Pressure Coefficients of Hydrogen and Helium at Constant Volume, and at different Initial Pressures. Part II. On the Vapour Pressures of Liquid Oxygen at Temperatures below its Boiling Point, on the Constant Volume Hydrogen and Helium Scales. Part III. On the Vapour Pressures of Liquid Hydrogen at Temperatures below its Boiling Point, on the Constant Volume Hydrogen and Helium Scales: Dr. M. W. Travers and others.—On Colour-Physiology of the Higher Crustacea: F. W. Keeble and Dr. F. W. Gamble.—On some Phenomena which suggest a Short Period of Solar and Meteorological Changes: Sir Norman Lockyer, F.R.S., and Dr. W. J. S. Lockyer. And other papers.

Linnean Society, at 8.—On Obesiella, a New Genus of Copepoda: Dr. W. G. Ridewood.—On Modern Methods in Mycology: Mr. G. Massee.—Further Observations on the Owls, especially their Skeleton: W. P. Pycraft.

FRIDAY, June 20.

Physical Society, at 5.—Exhibition of a Three-Circle Goniometer: G. F. Herbert Smith.—The Heat Absorbed when a Liquid is brought into Contact with a finely-divided Solid: C. J. Parks.—(1) On the Electrical Resonance of Metal Particles for Light Waves (Second Communication): (2) On a Remarkable case of uneven Distribution of Light in a Diffraction-Grating Spectrum: Prof. R. W. Wood.—Exhibition of a Simple Form of Apparatus for Measuring the Mechanical Equivalent of Heat: Prof. H. L. Callendar.

CONTENTS.

THURSDAY, JUNE 26, 1902.

BIBLICAL CRITICISM AT ITS BEST AND WORST.

Encyclopaedia Biblica; a Critical Dictionary of the Literary, Political and Religious History, the Archaeology, Geography and Natural History of the Bible. Edited by the Rev. T. K. Cheyne, D.Litt., D.D., and J. Sutherland Black, M.A., LL.D. Vol. iii. (L to P). (London: Adam and Charles Black, 1902.)

WHEN the plan of the "Encyclopædia Biblica" was first announced several years ago, the most favourable anticipations were formed with regard to the new project by all advocates of a moderate and scientific criticism of the Biblical writings. This dictionary was to embody the ideal of the late Prof. Robertson Smith, an encyclopædia which should include within its purview the results of the latest criticism, provided only that this criticism was conceived in common sense, developed with moderation and expressed with that consideration for the holders of traditional views which in this case is absolutely required. The first volume of the "Encyclopædia" seemed entirely to fulfil these anticipations, and its appearance was welcome to all students of Biblical history and archæology; but in the second, various disquieting symptoms were noticeable, especially in Prof. Cheyne's article "Jeraḥme'el"; the third can only be frankly described as disappointing these initial hopes and as being, in fact, most damaging to the cause of the "higher criticism." Those who have a working knowledge of Biblical criticism will, of course, be able to discriminate between those parts of the "Encyclopædia" which are really useful and suggestive and those which are the reverse; but what of the vast majority of readers who do not know? It is probable that very many of these, wearied by Prof. Cheyne's incessant discussion of his "Jerahmeelites" and "Muṣrites," irritated by Prof. van Manen's calm abolition of St. Paul and revolting against the inconsiderate tactlessness of Prof. Schmiedel's article "Mary," will, ignoring the vast overplus of sound and sterling critical learning which is to be found in the book, be driven into the opposing camp of anticritical obscurantism and refuse to hear anything further of Biblical criticism. Thus will the splendid work of critics of the type of the late Profs. Robertson Smith, Tiele and Socin, many of whose articles appear in this volume, of Profs. Driver, Nöldeke and Wellhausen, of President Moore and many others, be discredited by the insistent advocacy of a single over-mastering theory for which no convincing proof has yet been furnished by its author, and by the continual display by several of the continental contributors of their ignorance of the fact that in approaching British and American readers on such a subject as the Nativity of Christ or the life of the Virgin Mary the utmost tact is necessary.

We have spoken of Prof. Cheyne's insistent advocacy throughout this volume of the "Encyclopædia" of his Jerahmeel-*cum*-Musri theory, and have described this theory as one for which no convincing proof has yet been furnished by its author. Certainly in the "Encyclopædia Biblica" he has furnished none, either in the article "Jeraḥme'el" in vol. ii. or in the present volume. For a convenient summary of all that is apparently known about the name "Jerahmeel" and the tribe of the Jerahmeelites we may refer the reader to Mr. J. F. Stenning's paragraph on the subject in Hastings' "Dictionary of the Bible," vol. ii. p. 568. The Jerahmeelites were a clan of southern Judæa, mentioned three or four times in the Old Testament; the name Jerahmeel occurs four times (1 *Chr.* ii. 9, 33; xxiv. 29; *Jer.* xxxvi. 26). Prof. Cheyne, however, has built up for himself a vast edifice of pure theory all about the Jerahmeelites, in whom he sees a powerful tribe of Arabian origin equal in importance to, and rivalling, the Israelites. This theory is connected by him with Winckler's unproved theory of the existence of a North Arabian country bearing the same name in the Assyrian records as did Egypt and a land of Northern Syria, *i.e.* "Muṣri," which itself again largely rests upon the unproved theories of Glaser with regard to the age of the "Minæan" inscriptions of Yaman. So Prof. Cheyne pictures to himself hosts of "Jerahmeelites" and "Musrites" constantly warring against Israel, finding them even serving in the armies of Nebuchadnezzar; they were, according to him, constantly the objects of prophetic denunciation for the evil which they had done unto Israel, although at the same time a disproportionate number of the Jewish proper names known to us from the Old Testament are pronounced by him to be of Jerahmeelite origin. But if the Jerahmeelites are only mentioned half-a-dozen times in the traditional text of the Old Testament and the "Muṣrites" may quite possibly never have existed, how does Prof. Cheyne arrive at these somewhat revolutionary conclusions? By a simple process very characteristic of the extreme "higher critic," he merely supposes that the name "Jerahmeel" originally occurred far more in the Old Testament than it does at present, and that it has been constantly substituted and corrupted; he then proceeds to replace the words "Jerahmeel" or "Miṣṣur" (Muṣri) wherever he thinks they ought to stand, and in this way "restores" the text of the Bible in accordance with his theory. Many of his re-substitutions and corrections are founded on more or less ingenious emendations of the text; for others no justification is given; they rest merely on the *ipse dixit* of Prof. Cheyne. This procedure might be excused in a critic of such preeminent standing as Prof. Cheyne, and we would be ready to accept from the mine of his great learning many conclusions the reasons for which were not fully apparent were it evident to us that the steps of his reasoning were tending in the direction of what was both probable and possible; but in the case of "Jerahmeel" we confess that we have very little faith in his reasoning, and in the connected case of the supposed North Arabian *Muṣri* we believe that he has been misled by a hasty adoption of a theory which is in no way accepted by the majority of Assyriologists.

However this may be, it is in any case on the face of it evident that the professor has in the third volume of the "Encyclopædia" allowed himself to be absolutely over-mastered by his theory; he sees Jerahmeel everywhere; everything is a corruption or a disguise or a distortion

K

of "Jerahmeel"; *Amram* is a "development" of "Jerahmeel"; *Abram* is a corruption of "Jerahmeel"; *Levi* is a Jerahmeelite name, for it corresponds to Leah, which is "a fragment of a feminine form of Jerahmeel"; *Maacah* is "a popular corruption of Jeraḥme'el or Jeraḥme'elith (a Jerahmeelitess)," *Meholah* is the same, *Mephibosheth* (*col.* 3023), *Michael*, *Abihail* (*col.* 3198), *Jerubbaal*, *Ephrath* (3516), *Rimmon* (3379), *Ramah* (3264), *Jericho* (3258), *Hiddekel*, *Leummim* all apparently occur as corruptions of, or substitutions for, "Jerahmeel." In the majority of cases it is impossible to discover how or why. "Both *Micha* and *Chimham* [the italics are ours] (2 S. 19, 37 *ff.*) may quite naturally," says Prof. Cheyne (*col.* 3025), "be traced to Jeraḥme'el"; *Ebed-melech* ought to be "Arāb-jerahmeel" (3340); the *Nephilim* were really Jerahmeelites, for *Nephilim* = "Rephilim" = "Jerahmeelim"; and after this the transition *Nemuel*—"Jemuel"—"Jerahmeel" is comparatively easy! Further, *Amalek* is "an early popular distortion" (2935) of, and "ultimately the same name" (3258) as, "Jerahmeel." The inevitable Jerahmeel pursues us even into the Garden of Eden. In *Gen.* ii. 8 "we cannot hesitate to read 'Yahwê [Elohim] planted a garden in Eden of Jerahmeel'"; the traditional text reads, "And Yahwê [Elohim] planted a garden eastward in Eden." According to Prof. Cheyne there is a "Jerahmeelite form of the story" of Paradise (3574), and the passage *Gen.* iii. 20 probably ran originally, "And Jerahmeel called the name of his wife Hôrîth, that is, a Jerahmeelitess." The original names of Adam and Eve were, therefore, not Adam and Eve, but "Jerahmeel" and "Hôrîth." We cannot find that any real reasons are given for all these assumptions.

Dr. Winckler's hypothetical North-Arabian "Muṣri" is pressed into service in much the same way. Here is the traditional text of *Deut.* xxxiv. 1 side by side with Prof. Cheyne's version of it:—

Traditional Text. (R. V.)	*Prof. Cheyne's Version.*
"And Moses went up from the plains of Moab unto mount Nebo, to the top of Pisgah, that is over against Jericho. And the Lord shewed him all the land of Gilead, unto Dan, and all Naphtali, and the land of Ephraim, and Manasseh, and all the land of Judah, unto the hinder sea: and the South, and the Plain of the valley of Jericho the city of palm trees, unto Zoar."	"And Moses went up from Arabia of Muṣri to the top of the mountain of the Negeb of Jerahmeel [fronting Jerahmeel].[2] And Yahwè shewed him Jerahmeel as far as Dan, and all Tappūḥim [the land of Jerahmeel and Muṣri], all the land of Judah as far as the Jerahmeelite sea,[3] and the Negeb of Jerahmeel [the land of Jerahmeel, the land of Muṣri]."

Prof. Cheyne's note [2] is to the effect that the words in square brackets are to be regarded as glosses; note [3] states that this is the true original name of the Dead Sea.

Because, relying on his own arbitrary interpretation of ii. *Chron.* xxi. 16, Dr. Winckler boldly supposes a North-Arabian Kush as well as a North-Arabian Muṣri, Prof. Cheyne naturally follows, and so we find that the name of *Nehushta*, the mother of Jehoiachin, is corrupt; it ought to be "Cushith," a North-Arabian: her father was "Elnathan of Jerusalem"; this is very unlikely; "Elnathan" is of course wrong, and "Jerusalem" is in this passage a corruption of Jerahmeel! Of course Prof. Cheyne does not mean a corruption in the sense in which the word "lord" is a corruption of "hlaford"; he means that the text has been more or less wilfully altered from the supposed original "Jerahmeel" to the existing "Jerusalem." But he gives no real proof of any such corruption or of the validity of his supposition that the original text read "Jerahmeel."

Mordecai follows the rest; *Paddan-aram* ought to read "Haran (Ḥauran?) of Jerahmeel" (3523); *Daniel* "is most easily explained as a corruption of Jerahmeel," and with Daniel go *Babel*, *Nebuchadnezzar* and *Belshazzar*, the real original of the latter having been a hypothetical "Baal, prince of Miṣṣur" (3983). For Prof. Cheyne's apparent belief that the names of Nebuchadnezzar and Belshazzar have, in the Book of Daniel, been substituted for those of his hypothetical North Arabian heroes, and that the *mise-en-scène* of the story of Daniel is to be bodily transferred from Babylonia to the Negeb of Jerahmeel, no proof whatever is given.

The reader is invited to compare the accepted text of *Jer.* xxxix. 1 with Prof. Cheyne's version of it; *Nergal-sharezer* is, according to him, a corruption of "Mergal-sharezer" (!) which "proceeded from" '*shar Yeraḥme'el shar Miṣṣur*,' "the king of Jerahmeel and the king of Miṣṣur." He turns the Babylonian Nergal-shar-utsur, the Rab-mag, and other Babylonian officials into princes of Jerahmeel, Miṣṣur, Nodab, Cushim and the Arabians For these extraordinary proposals not the slightest justification is given.

For Prof. Cheyne the Book of Obadiah seems to contain a kind of Bacon-Shakespeare cryptogram all about Jerahmeel, and this is how he, with apologies for doing so, it is true, recasts the well-known sentence from Psalm cxxxvii.: "On the heritage of Jerahmeel we wept, remembering Zion." In Psalm cx., Prof. Cheyne restores an original text for verses 5–6 (R. V.), "The Lord at thy right hand shall strike through kings in the day of His wrath; He shall judge among the nations, He shall fill the places with dead bodies, He shall strike through the head in many countries," as follows:—

"The Lord will shatter Jerahmeel in the day of His wrath, He will judge mighty kings for the treason of their pride. The Lord will smite Geshur on the land of the Arabians; the kings of Rehoboth He will destroy, the princes of Jerahmeel."

It may be admitted that the received text is here corrupt, but we cannot see that the corruption goes very far or think it probable that the original sense of the passage quoted was very different from its present tenour; even as it stands, it is not nonsense, any more than is the Pisgah passage quoted above.

Finally, we may compare the received text of *Gen.* x. 10 *ff.*, describing the kingdom of Nimrod, with Prof. Cheyne's version of it:—

Traditional Text. (R. V.)	*Prof. Cheyne's Version.*
"And the beginning of his kingdom was Babel, and Erech, and Accad, and Calneh, in the land of Shinar. Out of that land he went forth into Assyria, and builded Nineveh, and Rehoboth-Ir, and Calah, and Resen between Nineveh and Calah. . . ."	"And the beginning of his kingdom was Jerahmeel in the land of Seir. From that land he went forth into Geshur, and smote Hebron, Rehoboth, Jerahmeel, and Beersheba, which is between Hebron and Jerahmeel."

In this passage we have a plain statement of a legendary account of the origin of the kingdoms and cities of

Mesopotamia, the foundation of which is in the legend ascribed to a half-mythical hero called Nimrod. It is impossible to see what grounds there are for any radical alteration of the text, yet Prof. Cheyne arbitrarily assumes that all the Mesopotamian names in the passage quoted are substitutions for names of obscure places to the south of Judæa, and he apparently does so merely because Nimrod is called a son of Cush, and Dr. Winckler thinks there was a country called Cush in northern Arabia. In this case we cannot but reject Prof. Cheyne's alterations, which seem to us entirely arbitrary, unnecessary and improbable.

We have by no means given a full list of the passages in the "Encyclopædia" which Prof. Cheyne devotes to "Jerahmeel" and the names which he would identify with it, but further enumeration would be wearisome. Space, too, fails us wherein to recapitulate the obvious arguments against the wildest of all Prof. Cheyne's proposals, *i.e.* to explain *Goshen*, *Pithom* and *Raamses* as names, not of Egyptian places, but of "the Negeb of S. Palestine or N. Arabia" (*col.* 3211), and so to deny, in effect, that there ever was any Israelitish sojourn in, or exodus from, Egypt at all, the exodus having been, according to him, an exodus, not from Egypt, but, of course, from the other country of the same name in northern Arabia! (see the article "Moses"). But here again Prof. Cheyne is merely following Winckler, whose theory on the subject he regards as "at any rate very plausible" (*art.* "Mizraim," *col.* 3163).

Now Prof. Cheyne is, of course, at liberty to hold this theory if he pleases, and to connect it with the equally vague and unestablished theory of Dr. Winckler about the "North-Arabian Muṣri" or with any other theory he pleases, but it is doubtful whether he ought to state it with such assurance of its validity in a work of this kind, which was intended to give its readers the matured results of a reasonable criticism, not necessarily the latest theories all hot. Prof. Cheyne has, however, in the majority of cases chosen to give his readers mere neoteristic theories instead of solid and *certain* additions to knowledge.

We cannot find that any of his colleagues have adopted Prof. Cheyne's views on the Jerahmeel question, with a single exception, and that a most unexpected one. It was rather startling to find the name of Mr. T. G. Pinches set down as that of one of the contributors to a dictionary which was designed to set forth the views of the higher critics and is partly edited by the most extreme critic of them all, for Mr. Pinches has hitherto been conspicuous for his resolute adherence to the opposing school of sentiment on these matters, and has, indeed, always been looked upon as a pillar of evangelical orthodoxy; but now, not only do we find Mr. Pinches writing an article in a heterodox encyclopædia, we even find him apparently accepting Prof. Cheyne's most heterodox theory, and admitting into his article the statement that "'Pul' or 'Phaloch' may be a corruption of Jerahmeel." The remark about a "southern Asshur" in northern Arabia, which occurs just above this, must be due to Prof. Cheyne, but Mr. Pinches ought not to have allowed it to appear in his article without comment. Apparently the land *Âšr* mentioned in the Minæan inscriptions *Gl.* 1083, 1155 (6th century B.C.) is meant; this may be Assyria itself, if it is not the land of Asir in *western* Arabia, between al-Ḥeǵâz and Yaman. Mr. Pinches's alternative suggestion that Tiglath-Pileser III. may have received the name "Pul" "on account of the Babylonian opinion of his character (cp. Ass. *bûlu*, 'wild animal')" cannot be accepted, because *bûlu* is a generic term for "cattle," and we do not suppose that any sensible Babylonian would have called a king or anybody else "a cattle."

However, although we may regret that this volume of the "Encyclopædia Biblica" has been made the vehicle of a wild and unproven theory, or rather group of theories, we ought not to allow this regrettable fact to prejudice us against the volume as a whole. When Prof. Cheyne can free himself from the baneful influence of "Jerahmeel" his work cannot be bettered; witness his article "Ophir," which finally disposes of the idea, started and still maintained by persons with but little archæological knowledge, that Mashonaland is Ophir. The article of Profs. Nöldeke, Buchanan Gray and Kautzsch on "Names" should be carefully read; it is of great interest and value. Prof. Driver's article, "Mesha," is thoroughly exhaustive and extremely interesting; we cannot but regret that only a single contribution from his pen is to be found in this volume. The articles "Persia" and "Philistines," by the late Prof. Tiele and Prof. F. Brown, and by President G. F. Moore respectively, are of the first order, especially the latter, which is thoroughly up to date, the author agreeing with all those writers who have recently treated of the subject in believing the Philistines to have been certainly of European, and probably of specifically "Ægean," origin. The traditional view that they came from Crete is borne out on the one hand by the Egyptian records of the wars and alliances of the *Purusati* and on the other by the lately ascertained fact that the "Mycenæan" culture had obtained a foothold in Philistia at some time between the fifteenth and twelfth centuries B.C. In this connection, Mr. J. L. Myres's remarks on Mycenæan finds in Philistia and on the influence of Ægean pottery-types on the native styles should be noted (art. "Pottery").

Prof. Eduard Meyer's "Phœnicia" is worthy of so distinguished a historian; Mr. W. M. Müller's articles on subjects connected with Egypt are, while critical, at the same time moderate, careful and informing. Evidently he will not have anything to do with the Jerahmeelite theory; he still believes Pithom to be Pithom in the Wady Tûmilât, and holds with the rest of the world that the Israelites once lived in the land of Goshen, which was in Egypt.

The Rev. C. H. W. Johns must also be congratulated on his non-adherence to the Jerahmeelite theory; at any rate, he treats *Gen.* x. 8 *ff.* as referring to Mesopotamia, not to Jerahmeel, and evidently continues to think that "Nineveh" means Nineveh and not Hebron (see above). His article "Nineveh" is good; we find nothing to object to in it except the statement that "Sir H. Layard by his explorations definitely fixed" the city "at Ḳuyunjik (1845–47 and 1849–51)." As a matter of fact, he claimed by his excavations to have proved that *Calah* was the site of Nineveh, and it was only after Hincks, Rawlinson and others had deciphered the inscriptions that the earlier

view of Rich, duly mentioned in its place by Mr. Johns, was shown to be correct.

Other articles which may be highly commended are those of Prof. Deissmann on "Papyri," which contains a most valuable discussion of the character of New Testament Greek, of Dr. Benzinger on "Law" and "Passover," of Prof. Prince on "Music," besides various contributions by younger English Semitic scholars, *e.g.* Mr. S. A. Cook and Mr. Maurice Canney. We also welcome several short contributions by Sir W. T. Thiselton-Dyer on botanical subjects and a paragraph on the flora of Palestine by Mr. H. H. W. Pearson.

We have touched but superficially upon the many articles in this volume which deal with New Testament criticism. It is a highly controversial subject, and if things have to be said which are likely to shock the feelings of the average Christian, they should at least be said as tactfully as possible. But it cannot be said that we find much tact in the contributions, already referred to, of Profs. van Manen, Usener and Schmiedel, for example. This is a pity, for it prejudices readers in this country against this kind of critical work, which, though often exaggerated in its methods and not seldom self-contradictory in its conclusions, is still deserving of careful attention and study.

The general editing of the "Encyclopædia" could be improved with advantage. The highly laudable aim of employing only specialists in certain branches of biblical knowledge to deal with questions connected with their own special studies has resulted in a certain irritating choppiness of treatment. Thus we get an article, "Purim," of which five paragraphs are written by Mr. Johns, one by Mr. Frazer and one by Prof. Cheyne. Mr. Johns tells us all he knows about the possibility of a Babylonian origin for the feast; Mr. Frazer discusses Mordecai and Marduk, Vashti and Esther and Ishtar, the mock-king of the Sacæa and the king and queen of the May; and Prof. Cheyne implies that Mr. Frazer is all wrong, because there never were any such names as Mordecai and Esther, which are simply corruptions of Jerahmeel and "Israelith," and the book of Esther originally referred, not to Babylonia or Persia, but "to *a captivity of the Jews in Edom*" (italics in original). At least, we understand that Mr. Frazer wrote § 6 of this article; it is signed with his initials. But a fact which militates against this theory is that in the paragraph in question "J. G. F." refers to himself always in the third person—J. G. Frazer thinks this or J. G. Frazer thinks that—and an editorial note at the bottom of *col.* 3980 says that the editors "have no hesitation in appending a sketch of J. G. Frazer's view. . . ." Is it their sketch or is it Mr. Frazer's? If it is theirs, why is it signed "J. G. F."? Prof. Cheyne often adds paragraphs with remarks of his own, chiefly about Jerahmeel, to the work of other contributors; one conspicuous instance is in the article "Moab," by Profs. G. A. Smith and Wellhausen, which is followed by Prof. Cheyne for two columns with an addendum correcting Wellhausen's work in accordance with the supposed results of the latest criticism, *i.e.* Muṣri and Jerahmeel.

The faults of this volume are, then, many and great, but, we repeat, this fact ought in no way to detract from the inestimable value of the immense overplus of sound learning which is to be found in it. Prof. Cheyne's own articles do not all stray into the paths of Jerahmeel by any means, and the large majority of the other contributors, who show no trace of Jerahmeelite influence, are experts in their own particular branches, and their splendid work must be regarded as redeeming the "Encyclopædia" from many of its faults.

The publishers have done their utmost; the typography and general get-up of the book are first-rate: it is a pity that their efforts should be so severely handicapped by the wild theorising of one of their editors and by the tactlessness of some of their less notable foreign contributors.

In conclusion, a word of commendation must be given to the excellence of the proof-correcting; we have hardly discovered any errors in this regard. A slip of the pen left uncorrected is, however, noticeable in *col.* 3165, *l.* 2 from the top, where "al-Miṣr" should read simply "Miṣr." The phrase "al-Miṣr" does not, apparently, occur in the Himyaritic (Minæan) inscription *Gl.* 1155 (=*Hal.* 535) which is here mentioned; only "Miṣr" or "Miṣran" is spoken of, the latter expression = al-Miṣr.[1]

THE FORAMINIFERA.

The Foraminifera, an Introduction to the Study of the Protozoa. By Frederick Chapman, A.L.S., F.R.M.S. Pp. xv + 354. (London: Longmans, Green and Co., 1902.) Price 9*s.* net.

THE contents of this book may be divided into two parts, general and special. Beginning with the latter, we find presented in a convenient form (chapters vii.-xvi.) an account of the families and genera of the Foraminifera. One species of each genus is described and figured, the conditions of its occurrence and its palæontological history being also given. The figures are reproductions of pen and ink sketches, and in most cases will no doubt enable the student to refer his specimens to their proper genera. Some are, however, too indefinite to serve even this purpose, and the attractiveness of the book would have been increased if more care had been taken to give something of the elegance and finish of the natural objects.

In dealing with the phenomenon of the occurrence of two or three plans of arrangement of the chambers which is presented by many forms in the growth of the individual test, the use of the words *bimorphous* and *trimorphous* is advocated. The terms dimorphic and trimorphic were originally applied to such tests, but now that it is recognised that the species of the Foraminifera present themselves under two forms, arising by different modes of reproduction, the words dimorphic and dimorphism have been, in accordance with customary biological usage, employed in the latter sense. Fresh words are therefore needed, as the author points out, for the use to which

[1] That Egypt, by the way, is here meant, and not any place in North Arabia, is evident from the inscription itself, which obviously contains a reference to the conquest of Egypt by Cambyses. We are strongly of opinion that M. Hartmann's dating of this inscription in *Zeitschr. für Assyriologie*, x. (1895), p. 32, is absolutely correct. Weber's defence (*Mitteilungen der Vorderasiatischen Gesellschaft*, 1901, 1, p. 22 *ff.*) of Glaser's later view, as altered and amplified by Winckler and Hommel, is weak. Weber also, like Prof. Cheyne, takes the existence of a North-Arabian Muṣri for gospel; we prefer to wait till Dr. Winckler has proved its existence, which he has not yet succeeded in doing, before we accept it.

these terms were originally applied. But *bimorphous* and *trimorphous* are objectionable, not only on account of the clumsy and hybrid character of the former, but because they may be taken to imply, by analogy with the use of the terminations *ous* and *ic* in chemistry, some relation with the phenomenon of dimorphism. The Latin equivalents *biformed* and *triformed* proposed by Rhumbler [1] are far preferable.

The most valuable part of the book as a contribution to the literature of the Foraminifera is the chapter on their geological range. Twenty years ago, Schwager summarised the information which had been accumulated on this head in the article appended to Bütschli's account of the Sarcodina in Bronn's Thier-reich. Since that date our knowledge has greatly extended, and to no inconsiderable extent as the result of Mr. Chapman's own investigations. The chapter ends with a tabular view of the range of the several families, in which it appears that all the main ones were represented in the Primary rocks, and that four of them (Textularidæ, Lagenidæ, Globigerinidæ and Rotalidæ) have been found in Cambrian strata.

The descriptive part of the book ends with useful practical directions, but no mention is made of the microaquarium, which has yielded such excellent results in the hands of Schaudinn, who invented it.[2]

The earlier chapters purport to give, as implied in the title, an introduction to the study of the Protozoa in general and of the Foraminifera in particular; and it is undoubtedly most desirable that workers in this group should have their eyes open to the general biological bearing of the phenomena which lie before them. To attain this end they must, however, go elsewhere. In these chapters there is no grasp of the problems presented, or of the conclusions which have been arrived at. On p. 11 we are told that the division of the nucleus "takes place either by the simple process of binary division or by the more complex and beautiful process of karyokinesis." The author thus ignores the process which has been observed in several of the higher forms (though it is, indeed, alluded to and figured further on), namely, the simultaneous breaking up of the nucleus or nuclei into fragments. Continuing the same sentence, the karyokinetic division of the nucleus is described as a process "in which the nuclear body is invested with strands of chromatin threads,"—whatever that may mean; but on turning to Fig. 10, which is given in illustration, we find two figures from Schaudinn's paper on the "Central-Korn" of the Heliozoa (*Verh. deutsch. zool. Gesellschaft*, Bonn, 1896), which represent stages, not of the karyokinetic division of the nucleus at all, but of the division of the central granule, a process preliminary to karyokinesis.

In chapter iv., on the shell structure of the Foraminifera, the author is more at home, but it opens with the statement that the arrangement of the segments of the shell is partially determined by the form of the initial or primordial chambers. The primordial chambers, whether they be microspheric or megalospheric, are nearly always globular or ovoid, whatever the arrangement of the succeeding chambers may be. How then can the arrangement be in any degree determined by their form?

We cannot pass over the omission (p. 53) of the name of Max Schultze, the author of the classical work "Ueber den Organismus der Polythalamien," from the list of those who since Dujardin have been pioneer workers on the group.

On the whole it must be confessed that the book is written in a slip-shod style, which in these earlier chapters is very marked; and in closing it one cannot but feel that the author would have been better advised if he had confined himself to the special treatment of the subject, for which he is well qualified, leaving the larger biological problems to other hands. J. J. L.

1 "Entwurf eines natürlichen Systems der Thalamophoren." (*Nachrichten der K. Gesellsch. d. Wissenschaften zu Göttingen. Math.-phys. Klasse*, 1895, Heft 1, p. 63.)
The reader is left in doubt as to the precise term advocated by the author, for on p. 48 "dimorphous" is used, but on p. 164 the word has become "bimorphous."

2 "Ein Mikroaquarium." (*Zeits. f. wiss. Mikroskopie*. Bd. xi., 1894, p. 326.)

UNORGANISED FERMENTS.

Enzymes and their Applications. By J. Effront. Translated by S. C. Prescott, S.B. Vol. i. Pp. xi + 322. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd.) Price 12*s.* 6*d.*

IN his work on "Enzymes and their Applications," Dr. Effront has presented us with book of great interest and value. The book, as he explains in his preface, is "a summary of the course at the Institute of Fermentation of the New University of Brussels." If the lectures are delivered in the style in which the book is written, we should very much like to be among his students.

Judging from his definition of an enzyme, Dr. Effront is in practical agreement, although he does not say so, with those who class the enzymes among catalytic agents. His definition is as follows:—

"The enzymes, soluble ferments, zymases or diastases are active organic substances secreted by cells, and have the property, under certain conditions, of facilitating chemical reactions between certain bodies without entering into the composition of the definite products which result."

But although it seems appropriate to class the enzymes with catalytic agents, yet there are certain substances which appear to have a catalytic action upon the enzymes. For example, on p. 118 it is stated that the addition of 50 milligrams of asparagin to starch which has been treated with amylase increases the saccharification, in a given time, nearly seven-fold.

In chapter iii., which treats of the "Manner of Action of Diastases," the different theories advanced to explain diastatic action are carefully reviewed. As an example we may cite the theory of Arthus, who, relying upon the discrepancies which exist between the accounts of many authors as to the properties of the various diastases, takes up the position that enzymes are not substances, but are properties of substances. Enzymes, indeed, bring about chemical changes, but so also do light, heat and electricity. Magnetism is a property of magnetised substances such as steel, but it cannot be obtained apart from the substance. The same reasoning applies to enzymes, which are only the properties of the substances obtained by precipitation or other means, and therefore a pure enzyme is impossible. On p. 66 Dr. Effront shows

how extremely sensitive the enzymes are to antiseptic and toxic substances; we have not heard of magnetism or electricity being affected in a like manner. But whatever the truth may be, it cannot but be admitted that our present knowledge as to what diastatic action really may be is incomplete and vague in the extreme. Possibly the elucidation of many of the difficulties will follow the preparation of a pure enzyme.

One difficulty encountered in studying the enzymes is the multitude of names which a single enzyme may possess, *e.g.* on p. 51 we are told that sucrase is variously called "glucose ferment, cytozymase, zymase and invertin." The chief reason for this diversity of names is that different investigators, having obtained from different sources a diastase capable of transforming cane sugar into invert sugar, have often been under the impression that they have come across a new diastase and have therefore invented a name for it.

Chapters v. and vi. deal with sucrase from a theoretical aspect, and chapter vii., on the fermentation of molasses, introduces us to the technical portion of the work. Although sucrase is not prepared commercially, it plays a very important part in fermentation, especially in the manufacture of alcohol from molasses.

Dr. Effront has evidently studied the technical part of the question with the same care which he has devoted to the scientific side. As a consequence the chapters on the technology of the enzymes should be very valuable to those interested in this branch of the subject. The space at our disposal forbids us to more than briefly notice some of the important applications of enzymic fermentation. There is an interesting chapter on "Panary Fermentation," and here one cannot but be struck by the fact that although the art of bread-making is one of great antiquity, yet we know very little as to what really does take place in the process of bread-making.

Chapter xviii. deals with the industrial application of "maltase" (the ferment of maize, which also occurs in small quantities in yeast) and the manufacture of glucose.

Chapter xxi. should be of great interest to chemists, as it treats of the "Ferments of Glycerides and Glucosides." Among the various enzymes here discussed, we notice "lipase," the active principle of the pancreatic juice, "emulsin," which occurs in almonds, and "erythrozyme," the ferment contained in the madder root. This chapter might with advantage have been extended, but, unfortunately, our knowledge of these very interesting substances is not yet very far advanced.

In conclusion, we must not forget the translator, Mr. Samuel C. Prescott, who has carried out his labours in a most satisfactory manner. F. Mollwo Perkin.

OUR BOOK SHELF.

Astronomischer Jahresbericht. By Walter F. Wislicenus. Band iii. Pp. xxxi + 671. (Berlin: Georg Reimer, 1902.)

The value of this work to astronomers and others interested in astronomical matters is now so well known, in spite of this being only its third appearance, that the present issue will be warmly welcomed. In the compilation of such an undertaking as this, Dr. Wislicenus and his co-workers are to be heartily congratulated, for they have brought together a very great number of most useful references and excellent brief extracts of all the more important publications of the past year. The volume now contains 671 pages, and the compiler informs us that this will probably be about its normal size. The second volume contained 552 references more than the first one, and the one before us shows an excess over the second by 193 references. This latter excess was chiefly due to the great number of papers on Nova Persei, which required 228 references alone. In future, to keep down the number of such references, the compiler proposes to include under one reference all those publications which appear during a year under the same heading and by the same author. This seems a very rational suggestion.

It may be mentioned that references are not only given to all the original publications, but also to all translations of such publications and astronomical articles which have appeared in various quarters. Thus, to take a case in point, we find that the communication by Dr. J. Hartmann to the *Sitz. der Kgl. preuss. Akademie der Wiss. zu Berlin* on "The movement of the Pole Star in the line of sight" was translated into English in the *Astrophysical Journal*, and was noticed in *Sirius*, *Die Natur*, *Astronomische Rundschau*, *Das Weltall* and the *Revue Scientifique*, their respective references being added in each case.

The book concludes with a capital index of names and brief tables of errata to the second and present volume. In addition to those mentioned in the present volume, which, by the way, are remarkably few in number considering the work involved, may be added "Norman" instead of "Normann" in references Nos. 1454 and 2131, and "nächste Maximum" instead of "jetzige Minimum" in reference number 1510.

In conclusion, it is hardly necessary to point out that no astronomical observatory or similar institution should be without this volume, which embodies in it all that relates to the recent progress of astronomical science, not only in this country, but over the whole world. That the work has in its third year become so complete is due to the untiring labours of Dr. Wislicenus and his co-compilers, and it is hoped that such may in the future be lightened by the endeavour of all interested in such a useful undertaking to remember to send them separate copies, reprints, &c., of published papers.

W. J. S. Lockyer.

Elements of Metaphysics. By J. S. Mackenzie. Pp. xv + 172. (London: Macmillan and Co., Ltd., 1902.) Price 4*s.* 6*d.*

Prof. Mackenzie is to be congratulated on having produced an exceedingly useful little book of a kind which has no precise counterpart in our current philosophical literature. Within the compass of less than two hundred small pages he deals very suggestively with the nature of the metaphysical problems, the methods of metaphysical science and its relation to the rest of our theoretical and practical interests, science in general, art, ethics, and religion. The aim of his discussion is not so much to indicate conclusions as to lead his reader to comprehend the nature of the problems to be solved and the methods of solution which are at our command. Hence the beginner in philosophy could hardly have a better introduction to what is, after all, the main business of philosophy, the practice of thinking intelligently for himself on the ultimate problems of knowledge. So far as the author's own conclusions in philosophy are put forward, they indicate a rare catholicity of view with a certain bias in favour of the line of thought, represented by Aristotle and Hegel among the great names of metaphysics, which insists upon development as the key to the understanding of the forms of existence. As might be expected from his choice of philosophical masters,

Prof. Mackenzie is an idealist in his general position, though he evidently realises the difficulties which beset an over-hasty idealism, and states his result in an avowedly tentative form. A. E. T.

Histoire des Mathématiques dans l'Antiquité et le Moyen Age. Par H. G. Zeuthen. Traduite par J. Mascart. Pp. xvi + 296. (Paris: Gauthier-Villars, 1902). Price fr. 7.

THIS translation of Prof. Zeuthen's well-known and deservedly popular work has been revised by the author, and several interesting notes have been added by M. Paul Tannery. The greater part of the volume deals with the mathematics of the Greeks, especially their geometry; the Elements of Euclid, in particular, are analysed in considerable detail, and discussed witb intelligence and sympathy. Conservatives who still rally to the cry of "Euclid, and nothing but Euclid," may be respectfully invited to study, with the help of such comments as Prof. Zeuthen's, the actual text of the Elements, which is now easily procurable in Heiberg's excellent edition. It ought, on the one hand, to increase their admiration of the Greek geometer, and, on the other, to convince them of the absurdity of supposing that a garbled travesty of a portion of his work is the best introduction to geometry to put into the hands of the English schoolboy. Another interesting section is that which deals with the mathematics of the Arabs. It is difficult to claim for them any very substantial contributions to the science; but they showed themselves apt pupils both of the Greeks and of the Indians, they kept the study of mathematics alive when Christian Europe was passing through its darkest age of ignorance and superstition, and they powerfully helped on the subsequent revival. To Moslem scholars, and their enlightened rulers, modern Europe owes a debt which is not always sufficiently realised. M.

A la Conquête du Ciel! Contributions Astronomiques de F. C. de Nascius, en Quinze Livres. Livre Deuxième (fascicule 6 et dernier.) Pp. 84. (Nantes: Imprimerie-Libraire, Guist'hau, 1902.)

M. F. C. DE NASCIUS has favoured us from time to time with copies of his astronomical contributions, which are to extend when complete to fifteen volumes. Since each volume consists of numerous parts, it will be easily understood that no inconsiderable task awaits the reader who aspires to a complete mastery of the author's methods and teaching. Only one small part of the second volume lies before us, but we confess that we are utterly unable to comprehend its purpose or to do justice to the ingenuity that apparently underlies its construction. The general conception seems to be remotely connected with Bode's law, but is far more difficult of apprehension, for with this is connected a discussion of the "triangle of divine harmony," while over the whole hovers a bewildering but awe-inspiring theme which is expressed as algorithmic. It will, perhaps, be sufficient to say that the object of the author, if object he has, is by some simple manipulation of figures to produce quantities that shall approximate to various astronomical constants, such as the periods and distances of the planets. For example, he sets out to establish or reproduce the period of sunspots, which he gives at 11·11 years. The triangle of divine harmony is, we are assured, admirably adapted for this species of discussion. This triangle happens, fortunately, to be right-angled, and two sides have the values 69 and 17·89. There is a good deal about the number 69, which we are very solemnly assured is equal to 64 + 5, and it is no doubt entirely one's own fault if he fails to correctly apprehend its true significance, but 17·89 seems to be introduced here for the first time, at least in this volume, and one may be excused if he fails to perceive its actual bearing. Our author handles these quantities in the following way. The area of the divine triangle is first found, this is then doubled to get a parallelogram, and the side of a square found the area of which is equal to the tenth part of that parallelogram. This side has for its numerical value 11·110! and the author congratulates himself on his success.

For many years, we are afraid, M. de Nascius has laboured on similar lines, which are destined to bring him or his readers little profit, but which he will no doubt pursue so long as he can trace his figures. It is nearly thirty years, he tells us, since he first placed a hesitating foot on the path which was destined to lead him to such brilliant discoveries. Let us hope that he has been frequently cheered by finding some close coincidence between his calculations and observed facts, and that his delight has been as keen as that experienced by other physicists who have trod a more legitimate road and been led to more valuable results.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mr. Marconi's Results in Day and Night Wireless Telegraphy.

READING a brief account of these results in the *Times* of June 14, I perceive that Signor Marconi advances in explanation of the greater distance at which night signals were received, that the day signalling is affected by diselectrification of the transmitting elevated conductor.

If—as I gather—Signor Marconi is referring to his observations made at positions in the Atlantic, west of England, the waves travelling westward, may not æther drift in the earth's orbital path be concerned in producing the effects observed?

The waves advancing against the orbital æther stream in the day time, with it at night, might be supposed to give rise to conditions analogous to those which affect the transmissibility of sound against or with a high wind. It will assist if we assume a retarded æther drift near the earth's surface and free motion above. But still, the difficulty in this explanation resides in the very great magnitude of the effects observed.

I write merely by way of suggestion, and in very considerable ignorance of almost every particular involved in this explanation.

Remarkable Sunsets at Madeira.

THE last few evenings we have witnessed here some beautiful sunsets, closely resembling the sunsets observed after the Krakatoa eruption, which I remember well, *i.e.* there is the same large area of beautiful pink haze in the west and high up in the sky at and immediately after sunset. The first sunset which I felt certain was of the above character I noticed on Friday, June 6. On June 10 and yesterday the display was particularly striking. There were indications, I believe, of the pink glow on one or two evenings before June 6, but as there were a good many clouds about it was difficult to feel certain of the special character of the sunsets. F. W. T. KROHN.

Funchal, Madeira, June 12.

THE INSTITUTION OF ELECTRICAL ENGINEERS' DEPUTATION ON ELECTRICAL LEGISLATION.

WE published an article a short time ago (NATURE, vol. lxvi. p. 35) on the report of the committee appointed by the Institution of Electrical Engineers to inquire into the cause of this country's backwardness in electrical industries, and stated that it had been decided to ask the Prime Minister to receive a deputation on the subject. This deputation, after being once or twice postponed, waited upon the President of the Board of Trade, the Right Hon. Gerald W. Balfour, M.P., on

Tuesday, June 17. A number of influential members of the Institution were present, including Mr. J. Swinburne (president), Lord Kelvin, Prof. J. Perry, Prof. S. P. Thompson, Colonel R. E. Crompton and Mr. S. Z. de Ferranti.

Lord Kelvin having introduced the deputation, Mr. Swinburne gave a clear statement of the case. He pointed out that local authorities had become involved in electrical enterprise through what was in reality only an accident, namely, that the laying of mains involved opening up the streets. As a result they had obtained legal powers which were not always used properly or in the interests of the community. Even a municipality acting in the true interests of its own ratepayers need not necessarily be doing what was best for the country at large. It was, moreover, now possible to carry out electrical undertakings on a scale that was not contemplated when the Acts by which they are governed (the Electric Lighting Acts of 1882–1888 and the Tramways Act of 1870) were passed. They urged, therefore, that the whole question of electrical legislation should be reconsidered by the Government with special reference to the right and advisability of allowing the municipalities to retain their present powers. This question concerned the Government as a whole, but there was also a matter concerning the Board of Trade in particular. It was thought that there should be a larger electrical staff to enable the Board of Trade to deal more satisfactorily with modern developments. Many of the regulations were behindhand, and it was thought desirable that some questions, such as the use of overhead wires, the size of transformers, &c., should be reopened.

Other speakers followed, including Colonel Crompton, who cited the case of Hove as one in which the Corporation had done its best to thwart the efforts of the company which was supplying electric light. Mr. Ferranti laid stress on the desirability of allowing the use of overheadwires so that the capital expenditure of pioneering schemes might be diminished, and urged greater flexibility in the Board of Trade regulations generally. It was finally agreed that the Institution of Electrical Engineers should go through the regulations and make recommendations to the Board of Trade on the points which electricians consider require amendment.

Mr. Gerald Balfour, in replying on the main question, admitted England's backwardness, but doubted whether it was entirely, or even chiefly, due to the cause alleged. We had to contend in England with the conservatism of strongly developed interests. He did not question, however, that the existing legislation was capable of amendment, and two Bills had already been drafted, one dealing with electric traction and the other with electric lighting. The Traction Bill was to give effect to the recommendations of the departmental committee appointed by the Board of Trade, and he hoped it would prove a satisfactory compromise between the wishes of promoters and municipalities. The Lighting Bill was based on the recommendations of the House of Commons Committee of 1898, which advised considerable modifications of the existing laws. He could not, however, hold out any hope of either Bill being passed this session. Mr. Swinburne asked that the whole question might be considered by a Royal Commission, and Mr. Balfour replied that he would be willing to consult the Cabinet, but could not say, without further consideration, whether he should recommend the suggestion to be adopted.

It need scarcely be said that this promise is quite insufficient to satisfy the urgency of the case. Indeed, the spirit of the reply to the deputation is not what should inspire statesmen who desire to encourage national progress. It is conceded that the obstacles to electrical development in this country are serious, and that they prevent our electrical engineers from keeping the nation in the forefront of progress. The obvious duty of an enlightened Government is to insist that difficulties in the way of industrial advances must be removed; or, at any rate, encouragement should be given to those who have to overcome them. Instead of this, our statesmen find excuses for the barriers across the road, and are eager to show reason why no attempt should be made to break them down.

Such justification as Mr. Gerald Balfour gave for masterly inactivity is almost sufficient to make anyone abandon hope that departmental officials will ever understand the needs of science and technical industries. What do they know of progress whose only desire is not to interfere with vested interests? Any advances that are made in England are due to the restless men who have in them the spirit of evolution and who force development in spite of unsympathetic circumstances. But we cannot hope to keep in line with other progressive nations unless the conditions for improvement are made more favourable. In commenting upon the apathetic spirit in which Mr. Gerald Balfour met the deputation, the *Times* referred to our leeway in electrical industries and expressed the views of many thoughtful men as to the need of making it up. The remarks are worth reproduction here, because they show that the position taken by the Government is one from which the interests of science and industry cannot be seen.

It is not merely by America that we have been completely beaten in electrical engineering. We are far behind continental countries as old as ourselves and having quite as many vested interests to deal with. The reason is that every continental Government keeps in touch with the best knowledge of the day, and habitually consults, upon every question involving the application of science, the highest scientific authorities it can find. Had the Government of this country learned to take that course the position of the nation at this moment would be incalculably better than it is. When it was suggested to Mr. Gerald Balfour that his Board of Trade electrical staff is not adequate for the duties thrown upon it, he was apparently unable to grasp the meaning of the criticism. What is meant is that, instead of relying upon inspectors who from the nature of the case were not originally the foremost men in electrical engineering, and who, again from the nature of the case, are not the men most abreast of the developments achieved since their appointment, the Board of Trade should be guided by the advice of the real experts and pioneers who are actually doing the things which its official experts can only criticise from their bureaucratically narrow standpoint.

This nation really has no chance in modern conditions unless official persons generally consent to recognise that there are a great many important subjects about which they know nothing, and which are in a state of such rapid change and development that no student, of the calibre which an official salary will attract, can possibly be and remain in a position to legislate about them. What we want is that the real practical and scientific intellect of the country should be called to the aid of the politicians and their official "experts." It is not by Boards of Trade, with their self-sufficiency, their timidity and their necessary ignorance of the later phases of development, that other nations have adapted their legislation to the progress of science. It is by giving intellect that advisory place in the framing of legislation which it will never seek by the politician's method of appealing to the ballot-box. The electrical, chemical, physical and biological questions, upon the solution of which so much modern progress and prosperity depend, deserve and demand the habitual consultation of the best men engaged in their study.

Men of science and leaders of industrial development are familiar with these opinions, and it is time that our statesmen regarded national needs from the same point of view. Unless this is realised the nation cannot hold its position in the industrial wars of the world. The Duke of Devonshire's Commission many years ago gave a warning that continued neglect of scientific and technical interests by the Government must lead to disaster, and we have persistently called for reform to prevent the loss that must come unless the views of our

political leaders undergo a complete change. If the awakening does not come soon, the task of making up for the years of forced inaction will be almost impossible to accomplish.

From what has been said it will be seen that no definite hope can be given of an immediately beneficial result accruing from the deputation. It serves, however, to bring the matter somewhat prominently to the notice of the Government and of the general public, and if it accomplishes nothing more it will in this have paved the way for future reform. It is desirable that the public should be educated to know the advantages which electrical engineers are ready and anxious to confer upon them, and why it is that these have not yet been bestowed. Thirteen years ago Prof. Ayrton, in his oft-quoted Sheffield address, predicted that a time was coming when the Sheffield grinder would work amidst beautiful surroundings, deriving the power he needed from a small electrically driven motor. The time is now ripe for the realisation of that prophecy; in some few places, indeed, it is already begun, but for its free and rapid development there are many abuses and much restrictive legislation which must be removed. For electrical distribution the days of the small station supplying a limited area are numbered, and with them the days of effective municipal control. So also with electric traction; wide-spreading tramways connecting town with town and running far out into the country districts are needed to bring about decentralisation and to help to solve the pressing problem of overcrowding. We can hardly expect the municipalities to effect these changes; the arbitrary boundaries of the areas they control have no reference to the suitability of these areas as units for electrical distribution, and their interests are, moreover, to a certain degree directly opposed to decentralisation. Thus, quite apart from any considerations of the purity of the management or efficiency of municipal electrical undertakings, it will be seen that there is good reason in many cases for looking for better results to the nation from company working. In the train of developments such as would follow the removal of restrictive legislation, we may hope to find the improvement of our position as manufacturers of electrical machinery. The country lacks neither opportunities nor electrical engineers capable of making use of them. We may therefore reasonably look to the development of electrical undertakings to confer a double benefit upon the country; directly, by increasing the comfort and health of the people, and by facilitating commercial work of all kinds; and indirectly by increasing the number and size of electrical factories, and so contributing to the wealth and prosperity of the nation and helping it in the struggle with foreign competitors.

REPORT ON THE TEACHING OF GEOMETRY.

THE immediate result of Prof. Perry's Glasgow address has been the appointment of two committees, the work of which is now near to completion. The British Association committee has, we believe, concerned itself with the more general aspects of the problem. The committee of the Mathematical Association, largely composed of schoolmasters, is formulating a set of detailed recommendations, of which the geometry section was published in the May number of the *Mathematical Gazette* (George Bell and Sons).

The Mathematical Association committee contains delegates from the chief public schools within easy reach of London; it has, therefore, something of a representative character. Its recommendations are very definite; as the editor of the *Gazette* remarks, "it is very desirable that mathematical masters and others should fully avail themselves of this opportunity of placing on record their views as to the proposed changes." The secretary of the committee, Mr. A. W. Siddons, Harrow School, Middlesex, will be glad to receive criticisms of the report.

The study of formal geometry is to be preceded by a substantial introductory course, in which the subject-matter of geometry is to be treated experimentally and inductively. The pupil is to be carefully trained in the use of simple mathematical instruments; he is to be allowed to convince himself of the truth of geometrical theorems by numerical measurements and calculations. In this way he will make his first acquaintance with the main facts of geometry. When he has thus gained familiarity with the subject-matter, he will be in a position to apply the machinery of logic to his knowledge; he will be able to enter, with his eyes open, upon the task of consolidating into a consistent whole the facts he knows. Throughout his whole course he is to treat problems of construction in a practical way; he is not to be content with describing how the thing is done, he is to do it.

Passing to the formal study of geometry, Euclid, or rather a skeleton Euclid, is to be retained as a framework. Large omissions are recommended, but the logical order is to stand.

Theorems are cut loose from the limitations of construction by the admission of "hypothetical constructions." For example, the *pons asinorum* may be proved by bisecting the vertical angle, and thus dividing the isosceles triangle into two triangles that can be shown to be congruent by Prop. 4. For it is obvious that an angle has a bisector, even though the method of constructing it with ruler and compass may appear later in Euclid; the bisector might be found equally well by folding the triangle in two.

Constructions are to be taken out of the formal course and treated in whatever order seems advisable. It is clearly absurd to keep to Euclid's order of constructions unless we are confined to the use of his instruments, an ungraduated ruler and a pair of compasses that cannot be trusted to transfer a distance.

The following order is recommended in teaching the *theorems* of the first three books:—Book i., Book iii. to 32 inclusive, Book ii., Book iii. 35 to the end.

The course is to be lightened by the omission of a considerable number of dull and obvious propositions, such propositions being found more especially in Book iii. Definitions are not to be taught *en bloc* at the beginning of each book, but are to make their appearance only when needed.

It is suggested that two locus propositions should be added to Book i.—the locus of points equidistant from two points, and the locus of points equidistant from two lines. This will enable the pupil to inscribe and circumscribe circles to triangles at an early stage.

Playfair's axiom is preferred to Euclid's; and illustration by rotation is recommended in dealing with angles connected with parallel lines, triangles and polygons.

After Book i. we are to pass to Book iii., which by the omission of Props. 2, 4, 5, 6, 10, 11, 12, 13, 18, 19, 23, 24 is reduced to very modest dimensions. To cover the ground of the omitted propositions there is to be a preliminary discussion of the symmetry of the circle about a diameter, which can be managed experimentally by folding the circle and pricking holes round the semi-circumference.

The "limit" definition of the tangent is allowed; and Euclid's three propositions 16, 18, 19 are condensed into one—"The tangent at any point of a circle, and the radius to the point of contact are at right angles to one another."

Book ii. is to be illustrated by algebra; and in order to simplify the geometrical proofs a rectangle is to be defined as a parallelogram with one of its angles a right angle. The use of the signs + and − is sanctioned.

For Book iv. we find the proposal "that all propositions be omitted, as formal propositions, except 2, 3, 4, 5, 10, and that these be taken with earlier books, the rest of the book being treated as exercises in geometrical drawing."

Coming to Book vi., it is recommended "that an ordinary school course should not be required to include incommensurables; in other words, that in such a course all magnitudes of the same kind be treated as commensurable." This at once relieves teachers from an enormous task—that of explaining Euclid's definition of proportion. There is now nothing to be said beyond that the ratio of a to b is the fraction a/b. To meet this change, two alternative proofs are given for vi. 1, though attention is called to the continental practice of making the proof of vi. 2 self-supporting.

With regard to areas, the tendency of the report is to make the treatment algebraic. Euclid vi. 14, 15, 16, 17, 23 contain merely the one fact that the area of a parallelogram is $ab \sin\theta$; nothing is gained by concealing this fact from the student. It is definitely suggested that "numerical" trigonometry shall be taught concurrently with Book vi. "In connection with the formal course, as soon as the proposition that equiangular triangles are similar has been proved, the sine, cosine and tangent can be defined (if this has not been done earlier in the experimental course). In order to make the meanings and importance of these functions sink deeply into the pupil's mind, numerical examples should be given on right-angled triangles (heights and distances); these should be worked with the help of four-figure tables."

"In accordance with the spirit of the above proposals, the committee suggest that the following proposition be adopted:—If two triangles (or parallelograms) have one angle of the one equal to one angle of the other, their areas are proportional to the areas of the rectangles contained by the sides about the equal angles."

"All statements of ratio may be made in fractional form, and the sign = used instead of the :: sign. In the ordinary school course reciprocal proportion should be dropped, and compounding replaced by multiplying."

The report may be described as an attempt, on conservative lines, to simplify the study of geometry and to make it interesting. If the attempt is judged to be successful, now is the time to make examiners unstop their ears.

C. G.

SEISMIC FREQUENCY IN JAPAN.

IN no country has seismology been more carefully nurtured than in Japan. At the University we find a professor and assistant professor of this branch of science; in the Meteorological Department there is a bureau controlling more than 1000 observing stations, and, lastly, there is a committee composed of engineers, architects and men of science who, as an aid to carrying on investigations which will lead to a better understanding of earthquake phenomena, are supported by a Government grant.

This body, since its establishment eleven years ago, has already published thirty-six quarto volumes in Japanese and eight in English, and it is to the last of these, by Dr. F. Omori, professor of seismology, to which we now refer. Unlike many of the volumes by which it is preceded, which treat of construction to resist earthquake effects and kindred branches of applied seismology, this particular publication deals with questions which are purely scientific. Its title is "Annual and Diurnal Variations of Seismic Frequency in Japan," the investigation of other periodicities being left for a future occasion.

The materials analysed are 18,279 entries contained in earthquake registers from twenty-six meteorological stations which are distributed in a fairly uniform manner over the Japanese Empire. These registers, which for the most part are dependent on instrumental observation, are discussed separately, and it is in consequence of this method of treatment that conclusions new to seismology have been reached.

The first out of a series of seventy-six curves shows the monthly frequency of earthquakes in Tokio. In plotting this, as in plotting curves for other stations, those months where the ordinary seismic frequency has been affected by "after shocks" have been omitted; that is to say, the curves represent the normal frequencies in various districts. These omissions, all of which refer to the settlements which follow destructive earthquakes, are carefully epitomised. Dotted curves drawn through the mean position of monthly curves show annual and semi-annual periods. A comparison of the curves for seasonal seismic frequency shows that these may practically be divided into two groups. In one group the maximum frequency is in winter, whilst in the other group the maximum frequency is in summer. When we turn to the geographical distribution of the stations the records from which give these curves, it is found that they are distributed over two distinct areas—those which show a winter frequency lie in a district chiefly shaken by earthquakes having an inland origin, whilst those where the greater number of disturbances are noted in summer occupy an area shaken by earthquakes having a suboceanic origin.

In an endeavour to explain this striking result, the annual, monthly and diurnal frequencies are compared with corresponding fluctuations in barometric pressure. The general result arrived at is that the curves showing the winter frequency follow those of changes in barometric pressure, from which it may be inferred that an increase in barometric pressure has a marked effect upon the yielding of a land area. With the curves relating to earthquakes of suboceanic origin, it is seen that the annual variation is the reverse of the barometric pressure on land.

With regard to diurnal variation in seismic frequency, Dr. Omori concludes that this is probably due to corresponding variations in atmospheric pressure, but such frequency is not confined to earthquakes originating on the land. Single barometric fluctuations, even if they amount to 20 mm., are not generally related to any marked increase in seismic frequency.

Although the last two observations apparently contradict the more important result indicating a relationship between fluctuations in barometric pressure and the seasonal frequencies of earthquakes originating beneath the sea and on the land, arguments are adduced to show how such contradictions may be harmonised.

The distinction in the rules which governs the frequency of earthquakes with these distinctive origins, now brought forward for the first time, may probably be emphasised when, rather than analysing the registers from different stations—the entries in which may frequently be common to a number of such stations—an analysis is made of registers of earthquakes classified according to their origins. As illustrative of such materials we may refer to a catalogue of about 9000 shocks, published as vol. iv. of the *Seismological Journal of Japan*, in which each entry is referred to a district from which the shock it represents may have originated.

In conclusion, not only do we congratulate Dr. Omori on this new departure in seismology, but we also congratulate the Earthquake Investigation Committee on the admirable manner in which it has presented its results to those outside the pale of eastern ideography.

J. MILNE.

THE WEST INDIAN VOLCANIC ERUPTIONS.

A FEW additional notes referring to the recent volcanic eruptions in the West Indies have been received during the past week. Sir W. T. Thiselton-Dyer has sent us an extract from a letter written on May 29 by Dr. Nicholls, C.M.G., of Dominica, and as it contains testimony from one of the leading scientific men in the West Indies, the statements it contains are of exceptional value.

Dr. Nicholls remarks that the volcanic phenomena in both islands were somewhat similar, but in the ejecta from the volcanic vents there were differences. Thus the lava (and its products, viz. pumice, scoriæ, mud, ash and dust) thrown up from Mont Pelée was of an andesitic nature, whilst from the St. Vincent volcano a light basaltic lava was ejected.

Evidence of the hot blast which accompanied the eruption has already been given. One of Dr. Nicholls's friends was a passenger in the s.s. *Roddam*. "When the red-hot hurricane struck the ship he was enveloped in flames, as his clothes were set alight, and in his agony he jumped into the sea, which was almost boiling, and was not seen again." As to the cause of this extremely high temperature and the instantaneous destruction of life at St. Pierre, Dr. Nicholls says:—

The eruption came suddenly and unexpectedly, and probably in a few minutes the 35,000 persons in the city of St. Pierre were corpses. It would appear that a sudden fissure was opened on the side of the mountain overlooking the city, and near to the Etang Sec on this flank of the volcano a large vent belched out lava, superheated steam and acid gases downwards on to St. Pierre and the roadstead. The flashing off into steam of the water imprisoned in the incandescent lava converted that lava into sand and dust before it reached the city, and the radiation of heat from molten rock at a temperature of above 1000° C. caused an incredibly hot blast that would create a red-hot hurricane—if I may employ such a term—that would kill people and animals instantly and that would cause all inflammable matter to burst into flame. This, from what I gather, is what really happened, and I do not think that poisonous gases or electrical phenomena are accountable for the destruction of life. You can imagine what is the enormous heat right over the vent of an active volcano. Well, St. Pierre practically for a short time was in such a position, the vent being directed laterally towards the city until the fissure was closed and the volcanic ejecta were again directed vertically upwards. Many persons were actually burnt in places by hot scoriæ and mud, but the blast of heat from the volcanic vent appears to me to account in the only satisfactory way for the details I have obtained of the conditions found in the living and the dead.

In connection with the eruptions, it is of interest to learn from the Meteorological Office pilot chart of the North Atlantic and Mediterranean for June that a year ago a report was received from Mr. Francis Watts, of the Government Laboratory, Antigua, showing that on May 5, 1901, the schooner *Kate*, from Barbados to Antigua, ran into a violent commotion of the sea 32 miles eastward of the south end of Martinique. There was no wind, and it was concluded that the phenomenon, which lasted four hours, was caused by a submarine eruption. The report is recalled as possibly bearing upon an early indication of the activity which culminated in the recent disasters. At 6 p.m. on May 9 last, Captain Hernaman, of the Royal Mail Steamer *La Plata*, when 100 miles westward of St. Lucia, observed a green coloured sunset, and at midnight dust was falling on board. At 10.30 p.m. on the same date, the ship *Anaurus* experienced a severe submarine earthquake in 4° 38′ N., 32° 28′ W., the sea being violently agitated, the shock lasting 30 seconds.

The *Daily Mail* correspondent at St. Lucia says it is certain that there have been some changes on the sea floor in connection with the eruptions. He adds:—

The colonel commanding the Royal Artillery and the colonel commanding the Royal Engineers at St. Lucia both saw an eruption in the sea off that island, the water being shot up into the air, accompanied by rumblings. This occurred two days in succession, and was noted by independent eye-witnesses.

Also, at Grenada, in the little harbour, near the Botanical Gardens, the water bubbled up as in a cauldron and rumblings were heard, but at Dominica all was quiet.

I may mention that when the *Pallas* was at Chateau-Belair on May 21, with Sir Robert Llewelyn on board, I noticed a bubbling in the harbour just twenty yards astern of us, but it was so slight I thought it probably a vent in the bottom of the sea letting off steam, but I called the attention of others to it.

Prof. Bonney exhibited a mounted specimen of volcanic dust from Mont Pelée at the meeting of the Geological Society on June 11. Notwithstanding the risk of generalising from a single slide, he expressed the belief that the ejecta of the Soufrière and Mont Pelée are generally similar. Both, compared with specimens from Cotopaxi, are more uniform in size. The travelled dust from the Soufrière is a little smaller than that from the actual summit of the Andean volcano, but coarser than similar material from Chillo (more than 20 miles), Quito (35 miles), Ambato (45 miles), Riobamba (65 miles), and the summit of Chimborazo, about the same. All these vary much more in size and run distinctly smaller, especially the last. That from Mattakava, Hick's Bay, New Zealand (which fell on June 16, 1886), is rather coarser, more scoriaceous, with fewer mineral-fragments (especially of pyroxene), to which a dirty glass is often adherent. The dust from Barbados, ejected by the St. Vincent Soufrière in 1812, is very much finer-grained, but contains the same minerals, though pyroxene is less abundant.

The St. Lucia Weather Report for May states that, from the 15th to the 20th, the whole island was enveloped in a light hazy mist, the result of volcanic ash suspended in the air. Traces of this ash could be seen on all foliage, it being apparently deposited more freely at night.

The harbour master at Bridgetown, Barbados, has collected from captains of ships information relating to falls of volcanic dust encountered at sea, and the following reports thus obtained appear in the *Agricultural News* of June 7:—

May 7, 8 p.m., schooner *Violo*, from Demerara, met the dust 70 miles S. of Barbados. 10 p.m., the Norwegian steamer *Talisman*, from Demerara, 150 miles S.S.E.

May 8, 2.30 a.m., barque *Jupiter*, from Cape Town, 830 miles E.S.E. Hour not stated, barquentine *Fanny*, from Pernambuco, 250 miles E.

May 9 (?8), 4 p.m., ship *Monrovia*, from Rio Janeiro, 240 miles S.E.

(Bearing and distance in each case from Barbados.)

It is to be hoped that all the captains collected samples of the dust, and that these will be available for analysis, as it is desirable to ascertain the characteristics of the ash according to the distance of its descent from the crater from which it was ejected, the coarser particles presumably descending at the shortest distances, the finer at the furthest.

Drs. Fleet and Anderson, the Royal Society's Scientific Commission to investigate the outbursts, were due at Barbados on June 9. The Secretary of State for the Colonies had cabled to Dr. Morris, the Imperial Commissioner, to meet them on their arrival.

Reports have been published of additional volcanic and seismic disturbances which have occurred during the past few days. A telegram from Martinique on June 19 states that a column of mud has been ejected by Mont Pelée and has fallen on Basse Pointe, destroying a number of houses and flooding the lower part of the village.

A message received at Calcutta on June 19 reports that an earthquake has shaken the whole ridge of the Himalayas from Simla to Chitral. The shock was not very violent, but nothing so extensive has been known before.

We have also to record that a violent earthquake occurred at Cassano Al Jonio (Calabria) in the morning of June 22, accompanied by subterranean rumblings. The population was terrified, but no damage was done.

THE ROYAL SOCIETY SOIREE.

A BRILLIANT company of ladies and gentlemen was present at the Royal Society conversazione last week. Many of the exhibits were the same as on the occasion of the previous conversazione on May 14 (see p. 83), but there were some others in addition, and these are briefly mentioned below.

Dr. Morris W. Travers showed apparatus for liquefying hydrogen. Hydrogen, when compressed at the ordinary temperature and allowed to expand, becomes warmer, while air under the same conditions becomes colder; at temperatures below -80° C., hydrogen becomes an imperfect gas, in the same sense as air, and undergoes cooling on free expansion (Joule-Kelvin effect). The gas, under a pressure of 120–150 atmospheres, passes through coils in the interior of the apparatus, which are cooled in solid carbonic acid and alcohol ($-78^\circ{\cdot}5$ C.), in liquid air (-185° C.), and in liquid air boiling under reduced pressure (-200° C.). It then enters a regenerator coil, and expanding at a valve at the bottom is partially liquefied. The liquid collects in a vacuum-vessel at the bottom of the apparatus; the unliquefied gas passes upwards through the regenerator coil, cooling the gas it contains, and returns to the compressor.

Apparatus for obtaining serial sections of fossils, and restorations of fossils in wax built up from serial sections, were shown by Prof. Sollas, F.R.S.

Prof. F. W. Oliver exhibited Stephanospermum and other fossil Gymnosperm seeds. All the seeds exhibited were from the permo-Carboniferous of Grand' Croix, near St. Étienne. They were preserved in silica, and showed remarkable preservation of detail. The majority of the sections were of *Stephanospermum akenioides*, the seed in which a pollen-chamber was first discovered by Brongniart in 1875.

Photographs of the Rocky Mountains of Canada, and objects collected, were shown by Mr. Edward Whymper.

The Silchester Excavation Fund Committee exhibited a series of objects illustrative of recent discoveries on the site of the Romano-British city of Silchester, near Reading.

Examples of telephotography in the Alps and Himalayas were exhibited by Prof. E. J. Garwood.

Dr. F. W. Gamble and Mr. Frederick Keeble had an exhibit designed to show the chromatophores and colour-changes of Crustacea.

Mr. W. Gowland showed Japanese pictures of Buddhist divinities and saints by old masters.

Mrs. E. Walter Maunder exhibited drawings from two photographs of the corona of 1901, May 18, taken at the Royal Alfred Observatory, Mauritius.

A series of photographs illustrative of old customs still extant in Hungerford, Knutsford and Corby was shown by Sir J. Benjamin Stone, M.P.

An attempt to reproduce an Aurora Borealis was shown by Prof. W. Ramsay, F.R.S. The spectrum of the Aurora Borealis has been shown to contain lines due to the pressure of krypton; the great majority of the lines, if not all, are coincident with those of the krypton spark spectrum. An electrode-less discharge in air gives a spectrum in which the leading green line of krypton, 5570·5, is distinctly visible at low pressures. This discharge can be deflected by a magnet, sending out streamers in the lines of magnetic force. The main phenomena of the Aurora are thus reproduced.

A model of the exploring vessel *Discovery* was shown by the Joint Antarctic Committee of the Royal Society and Royal Geographical Society.

Prof. H. L. Callendar, F.R.S., had on view (1) simple apparatus for determining the mechanical equivalent of heat, and (2) vacuum-jacket calorimeters.

Mr. Edwin Edser and Mr. Edgar Senior showed an experiment illustrating a paradoxical consequence of the wave theory of light. Light enters a glass prism, of which the angles are equal to 90°, 45° and 45°, by one of the mutually rectangular faces, the angle of incidence being equal to zero. It is then reflected from the hypotenuse face at an angle of 45°, which exceeds the critical angle. A photographic grating (3000 lines to the inch) is formed on the hypotenuse face, the rulings being parallel to the axis of the prism. The secondary wavelets which, according to the wave theory, are formed at the clear spaces, produce diffraction spectra, of which the first five or six are visible. If the grating were absent, no light could leave the hypotenuse face of the prism. Thus, light which cannot penetrate the face when the latter is clear is freely transmitted when parts of the face are rendered opaque.

The "Grubb" collimating telescope gun sight was shown by Sir Howard Grubb, F.R.S.

The West Indian Volcanoes Committee of the Royal Society exhibited specimens and photographs illustrating the fall of volcanic dust at Barbados on May 7 and 8. The principal constituents of the dust are magnetite, hypersthene, augite, plagioclase (anorthite-labradorite), small pellets of pumice, and fine powder composed of minute mineral particles and disintegrated pumice. On heating the dust to about 1200° C., the pumiceous constituent fuses, and the mass on cooling forms a vesicular rock allied to hypersthene-andesite, but exceptionally rich in crystals. (1) Microscopic slides are shown illustrating the composition of the dust:—(*a*) dust as it fell; (*b*) magnetite; (*c*) hypersthene and augite; (*d*) plagioclase; (*e*) pellets of pumice; (*f*) thin section of partially fused mass. (2) Photographs of vegetation covered by volcanic dust, taken at Barbados on May 8, by Mr. W. J. Freeman. The specimens were forwarded by Dr. Morris, of the Imperial Agricultural Department of the West Indies, to Prof. Judd, C.B., F.R.S. The charts were lent by the hydrographer of the Admiralty.

Specimens of volcanic dust from the West Indies were also shown by Mr. Henry Crookes.

Mr. E. J. Bles exhibited living tadpoles of the Cape clawed frog, *Xenopus laevis*, Daud. The remarkable transparency allows the course of the nerves, blood-vessels, muscles, &c., of the head to be easily studied in the living animal. A method of feeding, not hitherto described in the Amphibia, can be watched. Bred from specimens kept in Cambridge for more than five years.

A series of specimens illustrating the life-history of the *Trypanosoma Brucii* was shown by Mr. H. G. Plimmer. This organism is the cause of nagana, or the tsetse-fly disease in South Africa.

Colonel Bruce, F.R.S., and Mr. H. G. Plimmer, exhibited *Apiosoma bigeminum*, the parasite found in the blood of Texas fever of cattle.

New species of fairy flies (Mymaridæ) were shown by Mr. F. Enock. The species are all ovivorous, some laying their eggs in those of the water demons (Dytiscus); as many as seventy-two larvæ of one species have been found in *one* egg of *D. marginalis*. Living specimens, *in situ*, and possibly some emerging.

The Royal Society exhibited a bronze example of the newly founded David Edward Hughes medal, and a medallion of the reverse.

Dr. A. Dendy had on view specimens, sketches and photographs of Moriori workmanship from the Chatham Islands.

A series of otoliths, chiefly of living British fishes, both marine and freshwater, showing the various forms assumed in the different genera, was shown by Mr. E. T. Newton, F.R.S.

Prof. W. M. Flinders Petrie, F.R.S., exhibited a series of worked flints from Egypt.

Experiments exhibiting interference between portions of light from independent sources were shown by Dr. G. Johnstone Stoney, F.R.S.

During the evening, demonstrations, with the help of the electric lantern, were given by Prof. W. M. Flinders Petrie, F.R.S., on early civilisation in Egypt; Mr. J. Y. Buchanan, F.R.S., a series of lantern slides illustrating the performance of M. Santos Dumont's steerable balloon and the accident to it on February 14; and Prof. E. B. Poulton, F.R.S., on recent work upon protective resemblance and mimicry in insects, illustrated by three-colour slides.

NOTES.

A MEMORIAL edition of the scientific writings of the late Prof. G. F. FitzGerald, F.R.S., will shortly be published in the Dublin University Press series. The volume has been prepared under the editorial supervision of Dr. J. Larmor, F.R.S., and footnotes in elucidation or correction of the text have been added where necessary. It extends to about 570 octavo pages, together with 64 pages of an introduction, in part biographical and in part historical and explanatory, of Prof. FitzGerald's relation to contemporary science. As much of his stimulating and suggestive thought was published in journals not readily accessible, just as it flowed from his pen, this substantial collection of papers will in the main be fresh to physicists. Being a record of the activity of a mind that was always in the van of progress, it will also be of interest as a reminder of the paths of advance of physical science during the last quarter of a century.

IT is beginning to be recognised that scientific knowledge, and a progressive frame of mind are attributes which must be possessed by all who are preparing for the struggle of the future, whether in peace or war. In the debate upon the Navy Estimates in the House of Commons on Friday, the scientific aspect of the problem of naval warfare was mentioned, and we are glad to see that Mr. Arnold Forster referred to the importance of keeping it in mind. As to the part science ought to play, and the respect it ought to receive in the Navy, he remarked that he believed it to be true of the Navy, as of every large department, that we had not yet fully realised the position that science had taken, and was bound to take to a still larger extent, in this country and in the world. He did not know that that was peculiar to the Navy. He thought it was far less true of the Navy than it was of many other great departments of life.

AT the general meeting of the Zoological Society of London held on June 19, the gold medal of the Society was delivered by His Grace the Duke of Bedford, K.G., president, to Sir Harry Johnston, G.C.M.G., K.C.B., in consideration of his great services to zoological science while occupying various official posts in Africa and especially in commemoration of his discovery of the okapi. After the close of the meeting, the third of the series of zoological lectures for the present year was delivered by Prof. E. Ray Lankester, F.R.S., on the okapi and its position in the natural series. Prof. Lankester's memoir in the Society's *Transactions*, which contains a full account of all that is known of "the new African mammal" up to the present date, is expected to be ready very shortly.

THE annual general meeting of the Röntgen Society will be held on Thursday, July 3.

IN connection with the Egypt Exploration Fund, an exhibition of antiquities found by Prof. Petrie at Abydos, and by Dr. B. P. Grenfell and Dr. A. S. Hunt in the Fayum and El Hibeh, will be on view at University College from July 1 to July 26.

THE annual conversazione of the Institution of Electrical Engineers will be held at the Natural History Museum, South Kensington, on July 1. There will be a reception of the foreign delegates to the International Tramways and Light Railways Congress at 9.15 p.m.

SINCE May 3, 1832, when Louis Bonaparte, then President of the French Republic, decreed that the Pantheon was again to be considered a Roman Catholic Church, the great pendulum installed by Léon Foucault to afford a proof of the rotation of the earth has been laid aside. M. de Fonvielle informs us that workmen are now busy making preparation for a new series of demonstrations. The operations will be conducted under the supervision of M. Berget, assistant to M. Poincaré. The pendulum itself is a ball of lead weighing 27 kilogrammes, and was used in 1869 by M. Maumenée for observations in the cathedral of Rheims during several months. The new demonstrations at Paris will be given in a few days.

THE United States Senate has passed a Bill directing the President to purchase all the capital stock, concession, unfinished work and machinery, and other property of the Panama Canal Company for 8,000,000*l*. The President is further directed to acquire from the Republic of Colombia a strip of land six miles wide along the route, over which the United States shall have permanent control. The Bill next authorises the completion of the canal. If the Panama Company is unable to give a satisfactory title and Colombia refuses to cede the land, the President is authorised to construct a canal by the Nicaragua route. The *Daily Mail* states that since the Martinique disaster the supporters of the Panama Canal have persistently declared that the Nicaragua route passed through a volcanic country, and that the canal would be liable at any moment to be destroyed. This argument had a marked influence in gaining votes for Panama. The passage of the Bill does not end the canal controversy. The House of Representatives recently passed a Bill authorising the construction of a Nicaragua Canal, with only two dissenting votes, but it is believed that the Senate's decision in favour of Panama will now be accepted.

MR. F. FINN writes to us from the Indian Museum, Calcutta, with reference to the late Prof. V. Ball's identification of the Catreus of Ælian with the Himalayan monal-pheasant. This identification Mr. Finn regards as erroneous, and he adduces reasons for considering the Honduras wild turkey as the bird in question. Possibly specimens of this bird may have been obtained in Ælian's time by the natives of Hindustan from America by way of China. If, however, this explanation will not hold good, the somewhat startling theory is suggested that the Honduras turkey was once a native of India.

IN the U.S. *Monthly Weather Review* for January and February last, Mr. A. Matthews discusses at considerable length the term "Indian summer," and gives references to, and quotations from, numerous works relating to its use. In America this season is connected both by name and popular belief with the aborigines; but the term is said to date only from about the last decade of the eighteenth century, and has reference to a spell of warm weather occurring in the late autumn. The term appears to have reached Canada in 1821 and this country in 1830. This warm period is frequently referred to in meteorological text-books; Dr. Buchan points out that if easterly winds have largely predominated in autumn, and south-westerly winds begin to prevail at the end of November, or a little later, the weather is likely to continue exceptionally mild. These conditions occur nearly every year, and the beginning of the warm spell is popularly known in this country as St. Martin's summer.

THE *Agricultural News* of the West Indian Agricultural Department adopts a suggestion that Coronation day, should be marked throughout the islands as an arbor day. It points out that this is exactly the right season for planting purposes. In many localities the planting of ornamental shade trees would be of great public benefit, and at the same time add to the comfort and amenities of life in the tropics. Particulars are given as to the methods of planting, suitable trees and palms for the purpose being always obtainable at the Botanic Gardens.

IN connection with the abnormally cold weather which has prevailed over the British Isles, and to a great extent over Western Europe also, since the closing days of April, considerable interest attaches to the temperature of the surface water of the Atlantic during the month of April. The mean results, derived from a total of 4150 observations, are given on the pilot chart for June, just issued by the Meteorological Office. There appears to have been an almost complete absence of ice about the banks of Newfoundland, a fact which is emphasised by the sea water of that region being warmer than usual, the excess ranging upwards to as much as 6° in places. Westward of the thirty-fifth meridian, from 30° to 35° N., the temperature was also rather above the normal, but from the coast of Virginia eastward between these relatively warm patches, along what may be described, roughly, as the Gulf Stream course, there was a deficiency of temperature right across the ocean to our coasts, the eastern half of the Atlantic being below the average. Northward of the fiftieth parallel it would appear that there are no normals available for comparison with the present series, which is unfortunate, as the condition of the sea immediately to the west of our islands, between the Fastnet and Iceland, probably exercises an appreciable influence on our climate. Down to June 16, when the pilot chart went to press, there were still no ice reports of any importance on the banks, the latest being May 8, a piece of ice 4 feet square, one of May 5 relating to bergs stranded on the Newfoundland coast, north of Cape Race. The strait of Belle Isle was clear, but floes were drifting down the Labrador coast, so that steamers could not approach the strait from seaward. Iceland reports show that there has been a good deal of ice off the north-western part of the island.

THE result of an investigation by Mr. Maxwell Hall relative to the mean maximum temperature and the rainfall of Jamaica and sunspot frequency has recently been published officially at Jamaica, and has already been mentioned in these columns (p. 159). The temperature observations, a full account of which he gives in the paper, extend over the years 1881 to 1898, and to eliminate minor irregularities Mr. Hall employs for the yearly value the mean of the year and the means of the year each side of this middle year; thus, to take an example, the value for 1885 is the mean for the three years 1884, 1885 and 1886. The temperature variations found in this manner, when compared with the variation in the spotted area of the sun's surface, bring out a close relationship between these two phenomena. Thus it is observed that the temperature is at a maximum at sunspot minimum and *vice versâ*, and that this variation amounts to about 2° F. With regard to the variation of rainfall as deduced from a discussion of the yearly means of rainfall, Mr. Maxwell Hall has previously shown (NATURE, vol. xlix. p. 399) that up to the year 1887 there was a general resemblance between the sunspot curve and that of rainfall, the maxima and minima of the rainfall variations corresponding approximately with those of the curve representing the sun's spotted area, but there were certain irregularities which suggested that the old view that there was most rain at the maximum and least at the minimum of the eleven-year curve was only approximately true. The further discussion of the rainfall observations up to the year 1899 shows, however, that this apparent law breaks down completely. When in 1889 and 1890 the rainfall curve should have been at a minimum, in reality it showed a subsidiary maximum, while also when at the sunspot maximum of 1893-4 the rainfall should have been excessive, it was conspicuous by a great deficiency.

THE important aid that photography can render to the surveyor has recently been well illustrated by a paper read before the Institution of Mining Engineers by Mr. Arthur O. Wheeler, attached to the staff of the Canadian Topographical Survey. In this paper we have the actual experience of one who has been much engaged in practical surveying, and his notes having reference to the selection of stations and to the photographic processes necessary in the field are as valuable as those which deal with the after manipulation of the photographic enlargements and the production of the contour maps. The application of the photographic method is based on the consideration of the triangle, the angles at the base of which are formed by lines drawn from the two known stations, at which the perspective view of the country has been obtained in the camera, to the point which is to be projected, and which may be considered the apex of the triangle. Accuracy demands that the triangle should be well conditioned, and reaches its highest value when the angle at the apex approaches a right angle. There will be difficulties connected with the selection of suitable stations, difficulties in the identification of orientation points, which Mr. Wheeler makes no attempt to minimise, but a peculiar feature of the method is that it is best adapted to a country where the actual measurement in the field is tedious or impossible. It was pointed out in the discussion of Mr. Wheeler's paper that the method did not offer great advantages in a country of gentle slopes and rounded outlines, with relatively small differences in elevation, because of the uncertainty of locating the points on different photographs. But when the country possesses no inconvenient features, other methods are easy of application. Moreover, it was urged that the plotting of the points is more laborious than in the older methods of surveying. Mechanical devices based on the theory of perspective can do much to shorten the office work of plotting, and in any case this delay and expense are more than compensated by the rapidity of the field work and the employment of a smaller number of assistants required to remove obstacles in an untravelled country. The method has been employed practically in Canada, where the Topographical Survey has been carried into regions the severe climate of which renders it desirable to shorten as far as possible outdoor operations.

A CONVENIENT form of rectifier and interrupter for use with alternating currents is described by Dr. Guilleminot in the *Archives d'Électricité Médicale* for May. The current to be used is led through a vibrating reed, which carries at its free end a contact dipping in and out of a mercury cup. The reed is placed between the poles of a permanent magnet and is magnetised by a coil of wire which surrounds it; the coil is connected (in series with self-induction and resistance) as a shunt to the main circuit. A damping arrangement is also attached to the reed. The reed vibrates in synchronism with the alternating current, and as the contact only dips into the mercury when the reed is deflected downwards, the main circuit is synchronously opened and closed, thus converting the alternating into an intermittent direct current. The great advantage of the apparatus is the ease with which it may be adjusted; the mercury cup can be raised or lowered, thus regulating the time of closed circuit; the length of free reed can be varied, and the phase of the vibration relative to that of the alternating supply can be altered by varying the self-induction in series with the exciting coil. It is thus possible to open the circuit always at the most suitable point of the wave—which depends, of course, on the purpose for which the current is being used. The apparatus, which is said to give excellent results in X-ray work, is the invention of Prof. Villard, and is made by M. Chabaud.

THE *Zeitschrift für Elektrochemie* for May 8 contains an interesting article by Dr. A. Ludwig upon the fusion of carbon. After referring to Moissan's classical work on this subject, and to the famous French chemist's production of diamonds in the electric furnace, the author gives details of his own work.

Theoretical reasoning had led him to the belief that, working under sufficient pressure, it would be possible to melt carbon and to maintain it in the liquid condition, and actual experiment verified this theory. At a pressure of 1500 atmospheres, the arc between two carbons inserted in the pressure vessel failed, and not even an E.M.F. of 70 volts sufficed to carry the current across the gap separating them. The author's explanation of this phenomenon is, that the carbon had assumed the third allotropic state, and had in its passage into the liquid and transparent condition become a non-conductor. The difficulty of maintaining it in this condition was, however, great, and in some cases the phenomenon only lasted a few seconds. Attempts were made to obtain diamonds, by sudden cooling of the interior of the pressure vessel by an inrush of water, but although unmistakable diamonds were found amongst the hard grey powder that was obtained, the results were not altogether satisfactory. The apparatus used by the author in these investigations has been patented (English Patent No. 16908, 1900), and as circumstances have compelled him to relinquish his own investigations of the subject, he hopes that others may continue the experiments along the lines he has indicated.

The development of the large Beaumont oil-field in Texas, which is situated only sixteen miles from the coast, will probably lead to oil being much more largely used as fuel for engines than it has hitherto been. The possibility of a cheaper supply of oil is a matter that is of great importance to this country, and may lead to the increased use of motor cars for suburban traffic and for trade purposes. The oil will be conveyed from the oil-field to the coast by pipe lines, along which the oil will flow by gravity into tank steamers, the cost of conveyance to this country being not much more than a halfpenny a gallon. It has been found by experiment that four and a half barrels of oil, or 189 gallons, are equivalent to one ton of the best coal. Oil is now used largely in America as fuel. On the Southern Pacific Railway 300 engines have been adapted to burn oil, and it is anticipated that a very large sum will, in consequence, be annually saved in the working expenses. In Russia no other fuel than oil is used on the 1600 miles of the Trans-Caspian Railway.

In the *Proceedings* of the Royal Society of Victoria, of which we have just received part ii. of vol. xiv., 1902, geology dominates, and zoology is the only other science dealt with. The natural history of the country is attracting particular attention, as shown by papers on Crustacea, Polyzoa and Mollusca. Mr. T. S. Hall and Mr. G. B. Pritchard discuss a suggested nomenclature for the marine Tertiary deposits of southern Australia. Local names are always desirable for formations which cannot be expected to correspond in time with the stratigraphical divisions made in distant regions; and the authors are to be commended for using names peculiar to South Australia, despite the fact that they introduce the Werrikooian and Jan Jucian formations. Prof. J. W. Gregory gives an account of the geology of Mount Macedon, an isolated mountain ridge, which though forty miles distant is one of the most conspicuous features in the views from Melbourne. It consists of a volcanic pile resting on Ordovician rocks. The igneous outbursts may have commenced in late Cretaceous times, but there is no certain evidence. The mountain, however, probably marks the beginning of the great period of volcanic activity of which the last eruptions built up still existing craters, and of which records are preserved in the legends of the Victorian aborigines.

The *Journal* of the Franklin Institute (vol. cliii. No. 1) contains an account of the half-tone trichromatic process of colour-printing, by Mr. F. E. Ives. Until recently, all the finest colour-printing has been done by the chromolithographic process employing from seven to twenty stones with as many inks and impressions. It has long been thought that, in accordance with the trichromatic theory of colour vision, three printing surfaces, colours and impressions might be substituted for the seven to twenty of the lithographer, and that the preparation of these surfaces might be accomplished photographically. The only commercially successful development of this idea at the present time is by the employment of three half-tone process blocks made from a trichromatic negative colour record and printed with three coloured inks in the type process. Up to the present the quality of the product of this process has, however, been so uncertain that the process has been brought somewhat into disrepute. The author shows that conditions can be secured which make it possible to obtain the best results almost automatically.

In the *Scientific Transactions* of the Royal Dublin Society (vol. vii.) is a paper by Prof. Joly on sedimentation experiments and theories. The rates of settlement of suspensions from solutions containing ions in various degrees of concentration indicate that above a certain concentration the rate of fall of the surface of the suspension is fairly independent of the degree of concentration. Below certain concentrations a distinct surface to the descending suspension fails, and the sediment is only seen to collect from the bottom of the vessel upwards. A suspension precipitated at a concentration in the neighbourhood of this critical concentration does not again precipitate with a distinct surface if reshaken. On removing the electrolyte from such an "exhausted" suspension, it is found that the liquid is as effective as at first in producing surface if a fresh sample of the powder is used. On the other hand, the original powder will not again exhibit the formation of surface when treated with fresh electrolyte of the same strength, but requires a more concentrated solution to do so. The failure is, therefore, to be traced to some alteration in the solid particles, and on testing the fresh powder it is found to be electrically negative towards distilled water, whereas the used powder is neutral or nearly so towards its salt solution. The author advances a theory of the process of sedimentation to account for the observed phenomena.

"The Pioneers of Evolution, from Thales to Huxley," is the title of a pamphlet of 114 pages by Mr. E. Clodd, published for the Rationalist Press Association by Messrs. Watts and Co.

The Agricultural Department of the Cape of Good Hope has issued a catalogue of South African fishes (marine and fresh-water), drawn up by Dr. J. D. F. Gilchrist, the Government biologist.

In his report of the Ghizeh Zoological Garden for 1901, Captain Stanley Flower announces that two important additions have been made to the buildings, namely, the lion-house and the elephant-house, both of which were completed during the year.

In the June number of the *Zoologist* Mr. R. Service alludes to the change which appears to have taken place of late years in the habits of the black-headed gull, this bird being much more of a land-dweller than formerly.

We have received a copy of a reprint of an article from *Chambers's Journal* in which Mr. H. F. Witherby recapitulates the main facts connected with the migration of birds, adding a few observations made during his own travels in the eastern Sudan and elsewhere.

A supplement to the *Oxford University Gazette*, issued June 17, contains the report of the delegates of the museum for 1901. Among the more important additions to the collections is a "totem-post," about 36 feet in height, from Queen Charlotte Island, presented by Prof. E. B. Tylor. The Hope professor of zoology announces that the insect collection has

been very largely increased during the year, the most notable item being a consignment of specimens from Sarawak, presented by Mr. R. Shelford.

THE results of a redetermination of the atomic weight of uranium by Prof. T. W. Richards and Mr. Merigold are published in a recent number of the *Proceedings* of the American Academy of Arts and Sciences. Of previous determinations the only one worthy of serious consideration is that of Zimmermann, who in 1886 found the value 239·59. Zimmermann's method, based on the preparation of pure UO_2 and its conversion into U_3O_8, appears likely to give too high numbers, owing to the difficulty of obtaining the lower oxide free from occluded gases and also of oxidising it completely. After much preliminary work and a long search for suitable substances, Messrs. Richards and Merigold chose the analysis of uranous bromide as the basis of their method. The preparation of pure uranous bromide and its manipulation present considerable difficulties. Its analysis was effected by first oxidising it to uranyl bromide by means of hydrogen peroxide and then precipitating the bromine by means of silver nitrate. The results showed satisfactory concordance, and led to a conclusion expressed by the authors as follows:—"If oxygen be taken as 16·000 and bromine as 79·955, the atomic weight of uranium appears to be not far from 238·53." It is remarked that, although this number differs by more than a unit from that given by Zimmermann, the percentage difference (0·45) is smaller than many which have often been passed unheeded in the case of elements of smaller atomic weight. It is, however, a noteworthy difference, and the probability seems to be that Zimmermann's number was too high. The paper of Messrs. Richards and Merigold brings to light many interesting facts about the chemistry of uranium.

THE additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius*) from South Africa, presented by Mr. E. G. Williams; a Patas Monkey (*Cercopithecus patas*) from West Africa, presented by the Rev. E. Millar; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. W. S. Hewitt; a Serval (*Felis serval*) from Africa, presented by Mr. P. Hayton; a Ground Hornbill (*Bucorvus*, sp. inc.) from South Africa, presented by Mr. F. H. O. Wilson; a Senegal Turtle Dove (*Turtur senegalensis*) from West Africa, a White-fronted Dove (*Leptoptila jamaicensis*) from Jamaica, presented by Mr. D. Seth Smith; a Barn Owl (*Strix flammea*) European, presented by Mr. G. Dundas; two West African Pythons (*Python sebae*) from West Africa, presented by Lieut. Lamprey; a Long-nosed Crocodile (*Crocodilus cataphractus*) from West Africa, presented by Capt. Gibson; an Orang-outang (*Simia satyrus*) from Borneo, an Alpine Chamois (*Rupicapra tragus*) from Savoy, a Suricate (*Suricata tetradactyla*), four Cape Crowned Cranes (*Balearica regulorum*) from South Africa, two Grey Ichneumons (*Herpestes griseus*) from India, deposited; a Chimpanzee (*Anthropopithecus troglodytes*) from West Africa, purchased.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JULY:—

July 2. 6h. 27m. to 11h. 22m. Transit of Jupiter's Sat. IV.
2. 14h. 3m. to 14h. 52m. Moon occults δ^3 Tauri (mag. 4·2).
14. Minor planet Vesta in opposition to the sun.
15. Venus. Illuminated disc = 0·807. Mars = 0·979.
15. 10h. Mercury in conjunction with Neptune. Mercury 1° 34′ S.
15. 15h. Mercury at greatest elongation 20° 35′ W.
17. 13h. Saturn in opposition to the sun.
18. 8h. 51m. to 12h. 34m. Transit of Jupiter's Sat. III.
19. Saturn. Outer minor axis of outer ring = 16″·38.
19. 10h. 56m. Minimum of Algol (β Persei).
19. 10h. 58m. to 11h. 54m. Moon occults ρ^1 Sagittarii (mag. 3·9).
23. 14h. Mars in conjunction with Neptune. Mars 1° 37′ N.
25. 12h. 9m. to 15h. 51m. Transit of Jupiter's Sat. III.
27. 7h. Venus in conjunction with Neptune. Venus 0° 11′ N.
28. 14h. Venus in conjunction with μ Geminorum. Venus 0° 2′ S.
28–30. Epoch of the Aquarid meteoric shower (radiant 339°–11°).
30. 14h. 46m. to 15h. 28m. Moon occults *m* Tauri (mag. 5·1).
31. 21h. Venus in conjunction with Mars. Venus 1° 18′ S.

THE ANNA BREDIKHINE ASTRONOMICAL PRIZE.—The conditions of this new astronomical prize, founded by Prof. Th. Bredikhine in memory of his wife, are published in *The Observatory* for May. The prize is to be awarded for the most thorough investigations of any large comet, the investigations to be pursued on the lines followed by the donor in his own famous cometary researches.

OCCULTATION OF W LEONIS.—Mr. J. F. Cole, of Cambridge, Mass., writing to *Popular Astronomy* (June, 1902), notes an observed decrease in the magnitude of this variable double about one half-second before its occultation. He suggests that other observers might endeavour to discern the probable change of colour at the next occultation, which takes place at 9h. 21m. (Washington mean time) on July 7, magnitude 5·6, position angle 99°.

A REMARKABLE BOLIDE OBSERVED AT LYONS ON MARCH 19.—A correspondent of the Société Astronomique de France records the appearance of "a magnificent bolide" at 9.10 p.m. on March 19. The observer, who was situated at Lyons, states that the meteor first appeared in the neighbourhood of Arcturus and then travelled eastwards until lost in the haze on the horizon. Form, round; light, yellowish orange; magnitude, brighter than Venus; trail, none; duration, 2 seconds (*Bulletin de la Société Astronomique de France*).

NOTATION OF VARIABLE STARS.—At the suggestion of Mr. A. Stanley Williams, and with the idea of correlating the various notations, a list of eighty-one variables to which different names have been assigned in published lists of variable stars, has been prepared by Mr. H. C. Wilson and published in this month's *Popular Astronomy*.

Of the various systems of notation in vogue, Mr. Wilson favours that used in the *Annuaire*, where the first nine variables discovered in a constellation are named by the last nine letters of the alphabet in their normal sequence; the second nine variables discovered in that constellation are designated in the same way, but the suffix "2" is added to the capital letter, and so on for the third, fourth, &c., sets of nine. Thus the twentieth variable discovered in Sagittarius is catalogued as S^3 Sagittarii. As the author remarks, "This method is capable of indefinite extension without becoming cumbersome; but, unfortunately, it does not have the advantage of priority, nor of adoption by those who are doing the most valuable variable-star work," and he therefore suggests that the double-letter system, as adopted by the Variable Star Committee of the Astronomische Gesellschaft, should be universally used; further, he suggests that the assignment of the notation to individual stars should be left entirely to the Committee, and, for provisional purposes, he advocates the adoption of the notation now used in the *Nachrichten* when naming newly suspected variables, viz. to assign consecutive numbers and to add the year of discovery, *e.g.* 3, 1901.

STUDY OF BRIGHT POINTS AND CURVES.

THE study of "brilliant points and lines" is an application of the principles of geometrical optics which has not hitherto received the amount of consideration which it deserves, when account is taken of (1) the simplicity of the principles involved, (2) the elegance of the results obtained, and (3) the ease with which the subject can be studied experimentally. The writer of the present note has a dim recollection of having worked out in his undergraduate days a tripos rider in which it was required to find the equation of the bright curves seen

when a source of light was reflected from a metal surface covered with regular scratches or corrugations of a given form, but beyond this he does not remember having seen any other bookwork or examples on the same subject. A general investigation of the theory of brilliant points is now given by Mr. W. H. Roever in the *Annals of Mathematics* for April, pp. 113-128.

When a ray of light emanating from a source which we will call P_1 is reflected at any surface, and an eye is placed at another point, P_2, a point of the surface from which the reflected ray travels directly towards the eye appears luminous and is called by Mr. Roever a *brilliant point*. A mathematical investigation also involves the consideration of points from which the reflected ray travels directly away from the eye, and although such points obviously do not correspond to any visible phenomena, it is necessary to consider them under the name of *virtual brilliant points*. If the reflecting surface is a thin wire, a point P_0 will be a brilliant point if the lines P_0P_1 and P_0P_2 make equal angles with the tangent line to the wire at P_0. We thus get the notion of a brilliant point on a *curve*. Taking next a

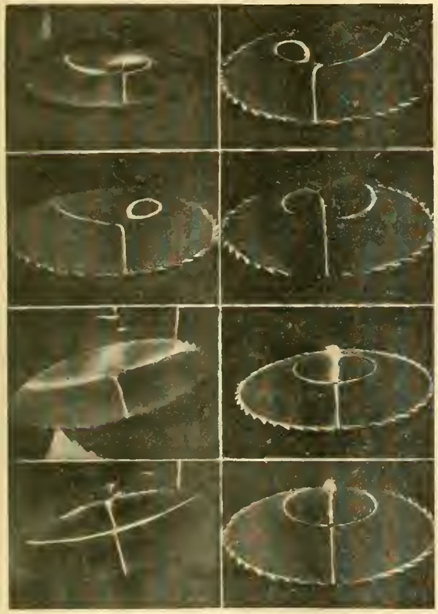

FIG. 1.—Bright lines on a circular saw.

finely but regularly scratched or corrugated surface, the locus of the brilliant points with respect to the curves defined by the scratches or corrugations is the brilliant curve of the system. For a doubly infinite series of curves, the equations of which contain two independent parameters, the mathematical theory leads to the consideration of a brilliant surface as the locus of the brilliant points, although it is not easy to see how this generalisation could be made the subject of experimental verification.

The author, after giving a general investigation, considers the particular cases of the brilliant curve for a circular saw or disc of steel in which the scratches form concentric circles, and also for a rotating carriage wheel in which the curve is generated by the brilliant points of the spokes, *i.e.* of a family of radiating lines in one plane. In both cases the curves are of the fourth degree. The accompanying diagrams are reproductions of photographs of some of the curves obtained with the circular saw. An obvious further example of loci of brilliant points is afforded when moonlight is reflected from waves or ripples on the sea or a lake.

VARIATION—GERMINAL AND ENVIRONMENTAL.[1]

"THE most critical and momentous period in the life-history of any plant or animal," says Prof. Cossar Ewart, "is during the conjugation of the male and female germ-cells." The variation which flows from this blending of the reproductive elements he speaks of as "germinal." That which occurs in the germ-cells up to the moment of conjugation, together with the variations during development and growth, he designates as "environmental."

It may perhaps be questioned in passing whether the distinction is one that can always be observed in practice, and also whether Prof. Ewart's terms are the best that could have been adopted. However, they serve sufficiently well for the purpose of the paper before us.

Some "congenital" characters, he proceeds, may be "acquired"; for example, dwarfing due to embryonic malnutrition. The double uterus of a wild rabbit contained eight young in one division and four in the other, the weight of the two divisions with their contents being nearly equal. In such cases the offspring that has been starved before birth, should it survive, may eventually reach the normal size and produce normal descendants. Antenatal injury, as in constriction by the cord, may lead to "congenital" abnormalities which are neither "inherited" nor transmitted.

Individual plasticity in response to environmental conditions is an obvious and undoubted fact. But can variations so induced be transmitted to descendants? This is still a burning question, in regard to which Prof. Ewart has as yet met with no evidence to support an affirmative answer. On the other hand, the results of his experiments have afforded much reason for the positive belief that the handing on in any form of acquired traits is extremely improbable.

But although there is no evidence of the transmission of somatic characters acquired in virtue of individual plasticity, it is still possible that the general vigour of the somatic tissues may be reflected in the germ plasm, and also that the condition as to ripeness of the generative products may influence the nature of the combinations formed during conjugation. A young Jacobin-barb pigeon mated with an old turbit produced first two young ones which were devoid of all the distinctive points of both parents; but afterwards, on several successive occasions, hatched out offspring which presented points of resemblance with the dam. Prof. Ewart declares that he can only account for this by saying that as the female parent increased in age and vigour her germ-cells increased in prepotency. When she went out of condition, the single offspring then produced more closely resembled the sire.

Some experiments with rabbits led to unexpected results. Several white does were mated with wild males, and several wild does with a white buck. In every case the offspring resembled wild rabbits in form and colour. But the mating of the half-wild offspring with each other, uniform as they were, led to an "epidemic of variation," not only in colour, but also in size, disposition and other qualities. When the half-wild rabbits were crossed with white bucks or does, there were also always several colours represented in the cross-bred litters. An intimate relation was discoverable in all these and their offspring of the next generation between the colour, the "wildness," the time at which maturity was reached, and the rate of growth. Though the half-wild progeny were all wonderfully like wild rabbits, it was evident that in them the stability of the wild rabbit had been broken down.

Further experiments with rabbits—one of which, narrated at length by Prof. Ewart, is of remarkable interest—tend to show that, as in the case of pigeons, the relative maturity of the male and female elements has a definite influence on the character of the offspring. The general results may be summarised as follows:—When insemination precedes ovulation, the young resemble the buck; when it follows, they resemble the doe; when it coincides, some take after the buck, some after the doe, while others may differ from both parents and resemble some of the less remote ancestors. It was incidentally shown that in the rabbit, spermatozoa may retain their potency several days after they reach the fallopian tube. Prof. Ewart notes the

[1] "Variation: Germinal and Environmental." By J. C. Ewart, M.D., F.R.S., Regius Professor of Natural History in the University o Edinburgh. *Scientific Transactions* of Royal Dublin Society, 1901 p. 353-378. (Williams and Norgate).

correspondence of the foregoing results with those obtained by Vernon in echinoderms.

The difference between different members of the same family must be in part attributed to the potential difference of the cells from which they are respectively developed. Whether the reducing division of the germinal cells is qualitative as well as quantitative is an open question, but there is reason to think that the life-history of these cells previous to conjugation may give opportunity for environmental variation like that of the Protozoa.

Turning now to the subject of "germinal variation," the author points out that the existence of such environmental variation in the germ-cells, apart from reducing division, together with the physiological differences dependent on diverse conditions of vigour and maturity, may be expected in most cases to preclude the new individual from assuming an exactly intermediate position between its parents. When the male and female germ-cells unite, a series of contests takes place between groups of vital units, the issue being decided by their respective qualities, individuality or character.

When different varieties or species are intercrossed, the effects may differ not only in degree but also in kind from those of ordinary cross-fertilisation. The following are some of the results that have been obtained experimentally from such intercrossing :—

(1) The offspring may be almost exactly intermediate between the parents.

(2) The offspring may resemble one of the parents and not the other. This is often the case when wild animals are crossed with tame varieties of the same species. (It must, however, be remembered that the resemblance may be only superficial, as was clearly the case in the experiments with half-wild rabbits cited above.)

(3) Some of the offspring may resemble one parent, some the other. (This seems especially likely to occur if one or both of the parents is a sport. Standfuss's results with insects are in accord with this.)

(4) The offspring may combine, almost unimpaired, the more striking characters of both breeds. This has been seen in both pigeons and rabbits.

(5) New or unexpected characters may appear in the progeny. Three out of four of a litter of cross-bred rabbits developed a habit of "spinning."

(6) When half-breeds are crossed, the offspring tend to be extremely variable. Evidence of this is plentiful both in animals and plants.

(7) Sometimes the offspring, instead of resembling the parents, resemble former ancestors. Prof. Ewart mated a cross between an "archangel" and an "owl" pigeon with a white fantail. The issue was a bird with a striking resemblance to the ancestral "blue-rock." (Analogous results have been several times obtained in the case of insects.)

Prof. Ewart's paper is interesting and suggestive to a high degree. It would be hard to overestimate the value of the experiments which he is conducting with so much care and judgment in his well-selected menagerie at Penycuik.

F. A. D.

RUST-FUNGUS.

PROF. MARSHALL WARD'S investigations into the relations between host and parasite in the case of the Brome-grasses and their rust-fungus are bringing to light some interesting facts which have important bearings on the long-vexed questions of wheat-rust and the rust problem generally, which, as is now well known, have passed into an acute stage of late, principally owing to Eriksson's enunciation of his belief that the fungus can be transmitted in an invisible form *viâ* the seed.

In addition to testing this mycoplasm hypothesis of Eriksson's, the researches undertaken by Prof. Marshall Ward are also directed to put to the proof the questions of degrees of specialised parasitism raised during the last decade by the researches of Plowright, Kleebahn, Eriksson, Magnus, Fischer, and others, and more especially, to see if any deeper insight can be obtained into the causes of epidemics and the relative predisposition or immunity of certain plants to attack.

In a paper read to the Cambridge Philosophical Society on January 20, 1902, Prof. Ward gave a summary of his results with more than eighteen hundred infection experiments, made on twenty-two species and varieties of Bromus with the Uredospores of *Puccinia dispersa* (Erikss.), the brown-rust of these grasses. These results show clearly that, other conditions being the same, the infection of a given species of Bromus—say *B. mollis*—by the Uredospores of the Puccinia depends on the origin of the spores, that is to say, on the circumstances of nutrition and breeding generally to which they have been hitherto accustomed. For instance, if the spores are reared on *B. mollis*, they infect another plant of *B. mollis* readily; but if they are reared on *B. sterilis*, they refuse to infect *B. mollis*, though they will readily infect another plant of *B. sterilis*.

But, in addition to the infective capacity of the spores conditioned by their past history, there is the question of the predisposition or immunity of the host. For instance, it is easy to infect *Bromus mollis* with spores from *B. mollis*, but far less easy to infect *B. racemosus* with such spores, and practically impossible to successfully infect *B. sterilis*. Part of Prof. Marshall Ward's work goes to prove that the immunity of given species of Bromus is not due to anatomical peculiarities, such as the number and size of the stomata, hairs, the volume of chlorophyll tissue and so forth, but to some substances or conditions in the living cells which escape microscopic investigation. In other words, the inquiry is being pushed into the domain of enzyme reactions, anti-toxins and so forth.

In a forthcoming paper it will also be shown that the external conditions of germination of the spores, and of infection by way of the stomata, require far more attention than they have yet received.

In a paper read to the Royal Society on February 20 last, another aspect of the investigation was opened up, namely, the possibility of obtaining pure cultures of these Uredines, a method which applies to other parasitic fungi as well.

In order to obtain more decisive answers to such questions as —Are any of the results obtained on plants in the open, or merely covered with bell-jars and so forth, due to spores accidentally introduced, or to mycelium, &c., already in the plant? a number of infections were made on seedlings germinated and grown antiseptically in tubes as follows :—

Clean picked seeds were placed singly, by means of forceps, on filter paper at the bottom of Petri-dishes properly sterilised by heat. When these had germinated, and observation showed that the whole series was free of moulds or other signs of contamination, the seedlings were removed by means of sterile forceps and transplanted singly into sterilised tubes of various kinds as described below, and the further growth allowed to proceed in the light under conditions varied as will be seen.

Prof. Ward had already shown that seedlings will continue to grow in such tubes, but, as we have seen, in the cases previously described he had no guarantee that the seedlings introduced into the culture-tubes did not already carry on their leaves wind-borne or otherwise transmitted spores.

In the case of these seedlings germinated from clean "seed" in sterile dishes and tubes, it is obvious that the only chance of infection depends on spores attached to the "seed" or on mycelium in the seed.

Experiments with seed gathered even from badly rusted plants and germinated as above have never given rusted seedlings, although other experiments have shown that the germ-tubes of attached spores can infect seedlings when the plumule is only 3–5 mm. high. Nor has Prof. Ward ever been able to discover any trace of mycelium in the seeds.

But if the "seed" of the Bromus is sterilised before germination—as can be done by steeping in various antiseptics, or by heating to 60–70° C.—it is found that pure cultures of the Brome may be obtained in the tubes, and it is then only necessary to infect such a clean seedling with the spores of the parasite to obtain a pure culture of the latter.

Preliminary experiments soon showed that the Brome seedlings thus raised from seeds treated antiseptically, and protected from the first by glass, may be grown for weeks and even for a couple of months in such tubes under proper precautions, and Prof. Ward set himself the task of ascertaining how such cultures would behave in infection experiments.

In the following experiment upright tubes of the kind known to chemists as "drying towers" were prepared as in the diagram (Fig. 1), so that by means of an aspirator attached to the tubing at G, a continuous current of damp air could be slowly drawn through the whole series, aërating the roots of the seedlings F, which burrowed into the cotton-wool B, day and night. The tubes were charged each with one seedling,

grown from seeds heated to 65° C., and forty-eight hours after germination had begun and the latter allowed to grow in the light on a table outside the laboratory. The tubes were charged on June 14, and on June 19, when the first green leaf was well developed, the latter was infected at a definite spot with spores

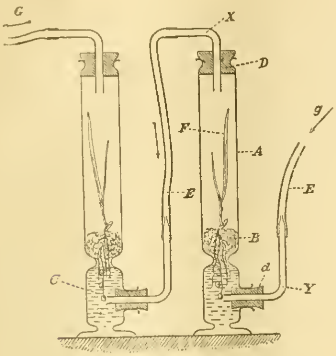

FIG. 1.

Diagram showing arrangement of tubes for pure cultures of grass seedlings—see text—here shown connected up for aëration. Reduced.
A = glass jar. B = cotton-wool saturated with liquid. C = liquid reservoir containing nutritive culture solution, through which air bubbles pass. D and d = caoutchouc stoppers pierced by glass tubing. EE = caoutchouc tubing. F = seedling with its roots in B and its leaves in air. G and g = arrows showing direction of air current. x and y = glass tubes.

—proved to be capable of vigorously germinating by cultures in hanging drops—and the whole series linked up and aërated. The growth of these seedlings in the moist air-current was very satisfactory, the plants having a deep rich green colour, though the leaves were short, and the results, as shown in the following table, were very instructive.

In this series the liquid employed was the normal Knop's mineral solution (+), so well known as used in water-cultures. The tubes were charged with this before sterilisation, enough being put in to wet the cotton-wool plug (B) and fill the reservoir (C), the side-tube y being fused at its pointed end during sterilising.

Since each tube is linked to its neighbour with clean flexible tubing, and the air bubbles through the liquid in the reservoir (C) and has to pass the cotton-wool plug (B) before reaching the leaves (F) in the air above, there can be no question of infection from outside, and the results also show that *infection only occurs exactly where the spores are placed* on the leaf in each case.

The spores employed were carefully tested as regards their germinating power, and, as the table shows, the results in the closed tubes fully bear out previous experience. In the aspirated tubes, however, the second pair of seedlings of *B. mollis* (No. 712) gave negative results, inasmuch as only flecks, and not pustules bearing spores, were developed. In the closed tubes, however—see below—the positive results, especially on *B. velutinus* and *B secalinus*, were excellent, and subsequent examination showed that the spores germinated well and were capable of infecting other seedlings.

In order to test further the behaviour in mineral solutions, Prof. Ward prepared, as the table shows, several series in closed tubes, Nos. 713, which served as a parallel series to Nos. 711 and 712, but without aeration.

In No. 713 the sterile seedlings were raised antiseptically as before, but the roots merely penetrated cotton-wool saturated with Knop's solution, and held by the constriction over the bulb filled with the same, no air being drawn through. The growth was excellent, and the results very conclusive, as the table shows.

The seedlings were allowed two days at 22–20° C. in the laboratory and then put out side by side with 711 and 712 in full sun during the middle of the day, and after two days' further growth were infected.

By the tenth day the thin leaf was well developed, and the first pustule was seen on *B. mollis* and *B. secalinus* on the eighth day after infection.

The growth of pustules was excellent on *B. velutinus* and *B. secalinus* especially.

This experiment is interesting, not only as showing that plants can be grown and infected successfully in these closed water-cultures, but especially as showing the contrast between the aerated and non-aërated tubes, for, since the infected

seedlings were selected in each case from the same Petri-dish cultures, we must assume that the difference in rate of development was due to the difference of ventilation, and perhaps conclude that this interferes with the success of the parasite, as measured by the somewhat longer incubation period. It is remarkable how dwarfed the continuously aërated plants are, compared with those in closed tubes, owing to the elongation of the leaves of the latter.

It is clear, therefore, that pure cultures of Uredospores can be obtained by this method, and it is equally clear that we can also obtain pure cultures of the host-plants, and since we can do this, there is no reason why the infection of Uredineæ should not be conducted as rigorously and exactly as that of bacteria. As a matter of fact, Prof. Ward has succeeded in proving that it can,[1] though of course the length of time occupied in a large series of cultures and infections will prove troublesome, and it remains to be seen whether we can get such plants to flower (see Fig. 2).

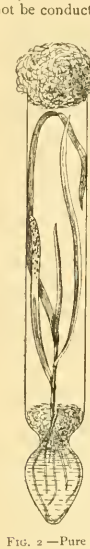

FIG. 2.—Pure culture of *Puccinia dispersa* on *Bromus velutinus*. The "seed" of the grass, antiseptically sterilised as regards fungus spores by heating to 65° C., was germinated in the sterile tube and infected on the first leaf with spores developed on *Bromus mollis*. The infection was successful, and pustules of spores have appeared *only on the area inoculated.*

A number of isolated tube-cultures were made with spores from *B. sterilis*, *B. mollis* and *B. secalinus*, and arranged similarly, and confirmatory results obtained. Moreover, Prof. Ward was able in several cases to transfer successfully spores from these pure tube-cultures to other tubes of pure cultures of seedlings, and to prove that the spores raised under strictly antiseptic conditions are capable of germination and infection.

At the same time, it was noteworthy that in several cases the antiseptically raised spores were not always successful in infecting the seedlings, and it remains for further investigation to determine whether this was due to the conditions of culture of the fungus or the host, or both.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A DISCUSSION upon the clause of the Education Bill referring to the provision to be made for secondary education took place in the House of Commons on Monday. An amendment was moved to make the clause compulsory instead of optional, the contention being that many local authorities will do nothing for secondary education if the decision as to the needs of their localities is left to them. After discussion, Mr. Balfour consented, as a compromise, to introduce words which, while not making the clause mandatory or throwing upon the Education Department the task of declaring what educational provision should be made in each county, emphasised the fact that the education authorities were expected to supply higher education. The words to which he agreed were:—"The local authorities shall consider the needs of education, and take such steps as may seem desirable, after consultation with the Board of Education, to aid or supply education other than elementary."

THE following teachers have been appointed by the Senate of the University of London, in connection with the grant of 10,000*l.* a year recently voted to the University by the London County Council in aid of the work of the faculties of arts, science, engineering and economics:—Prof. Ramsay, F.R.S., teacher of chemistry, at University College; Prof. Capper, teacher of mechanical engineering, at King's College; Prof. Unwin, F.R.S., teacher of civil and mechanical engineering, at the Central Technical College.

AN anatomical museum, endowed in memory of the late Prof. A. Hughes, was formally opened at the South Wales and Monmouthshire University College on Saturday. Prof. Hughes, who died of enteric fever contracted in South Africa, was the first occupant of the chair of anatomy at the College, and when he left to take a similar position at King's College, London, he gave 350*l.* with which to purchase the nucleus of the anatomical museum. To his memory and in recognition of his special services to medical education in Wales, it was decided to endow the museum permanently, and a fund was opened, towards which 1775*l.* has been subscribed. Of this amount 120*l.* has been set apart for the foundation of an Alfred Hughes medal, to be awarded annually in the subject of anatomy.

A VERY creditable display of pieces of simple scientific apparatus was to be seen in connection with the annual exhibition, at the Examination Hall on the Thames Embankment, of specimens of work by the pupils and teachers in the schools of the London School Board, which was opened on June 18 by Lord Reay, chairman of the Board. Compared with the exhibition of November last, which was reported in NATURE (No. 1671), a marked improvement has to be recorded. There were three times the number of exhibits, and the general standard of excellence was much higher. Many of the defects of the last exhibition were remedied in that of this year. More attention was given to the different branches of physics, and in place of the three more or less unsatisfactory models representing the teaching of physiography, which were all that we could find last time, ten times as many better pieces of apparatus were included, among which a good model of Foucault's pendulum, an astronomical telescope and a relief map of Sydenham—the last-named by a couple of boys of eleven and thirteen years of age—deserve special mention. The chemical section provided abundant evidence of the influence of Prof. Armstrong on the teachers of this subject. It was clear from the exhibits in this department that every effort is being made to develop the child's intelligence by encouraging him to discover facts for himself. Though more attention was given to nature-study than was the case last year, there is still plenty of room for development in this direction. The undesirable plan of mixing up the work of teachers and taught was followed again, but it is to be hoped that the committee of management may be persuaded, before holding another exhibition, of the difficulty experienced by the visitor in knowing, without consulting a bulky catalogue, when an exhibit is the work of a pupil and when that of the instructor. It is impossible in this place to describe the exhibits in detail, but a good Wimshurst machine constructed by a boy of fourteen was an excellent instance of the trouble a youngster will take when once he has been interested in the subject of study.

SCIENTIFIC SERIALS.

American Journal of Science, June.—Fossil faunas and their use in correlating geological formations, by Henry S. Williams. It is shown that the plan usually followed of classifying geological formations in time by means of a comparison of one predominant fossil is wanting in accuracy. Very many single species, the range of which has been established by thorough study of the successive formations in which they occur, range through a third, and often a half, of one of the standard geological systems. A second reason for not resting implicit confidence on this method of correlation is the frequently observed fact that parts of the geological column of different sections, which upon satisfactory stratigraphic grounds are known to be stratigraphically equivalent, contain different fossils.—Studies of the Eocene mammalia in the Marsh collection, Peabody Museum, by J. L. Wortman. The present instalment of this series contains detailed descriptions of *Sinopa rapax* and *Sinopa agilis*.—The transmission of sound through solid walls, by F. L. Tufts. The rigidity of the material was found to be the main factor in determining the intensity of the sound transmitted from the air on one side to the air on the other, the only other factor possessing any influence being the mass.—A new gauge for the measurement of small pressures, by E. W. Morley and C. F. Brush. A description of a form of differential mercury pressure gauge resembling in principle that recently described by Lord Rayleigh. Two modes of reading are given; in the second method a reading can be taken in ten seconds. With suitably mounted instruments pressures may be read with a mean error of not more than a ten-thousandth of a millimetre.—On a hitherto untried form of mounting either equatorial or azimuth, for a telescope of exceptional size, either reflector or refractor, in which telescope, observing floor and dome are combined in one,

[1] *I.e.*, of course so far as fungi are concerned; the antiseptic treatment adopted does not always exclude harmless bacteria.

by D. P. Todd.—On the occurrence of uranophane in Georgia, by T. L. Watson.—The internal structure of cliftonite, by J. M. Davison. The view of Fletcher that this form of crystallised carbon is a pseudomorph after pyrite is not confirmed by these experiments.

Journal of Botany.—The June number opens with notes on Mycetozoa by Mr. Arthur Lister, F.R.S., and Miss G. Lister. Two species are figured and described; of these *Physarum gyrosum* is allied to *Fuligo septica*, while the other, *Chondrioderma asteroides*, is a new species which was found on pine needles and acacia leaves at La Mortola. In addition, the nomenclature of certain Mycetozoa collected by Dr. Celakovsky in Bohemia is discussed and revised. To the lists of Sussex plants already published by Mr. E. S. Salmon and Mr. Whitwell during the past half year is added another referring mainly to the west Arun district of west Sussex, contributed by Rev. E. S. Marshall. The catalogue of British marine algæ compiled by Mr. Batters which began in the March number has now reached the genus Ectocarpus.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 15.—"On Microscopic Effects of Stress on Platinum." By Thomas Andrews, F.R.S., F.C.S., and Charles Reginald Andrews.

The microscopic effects of stress on platinum do not appear

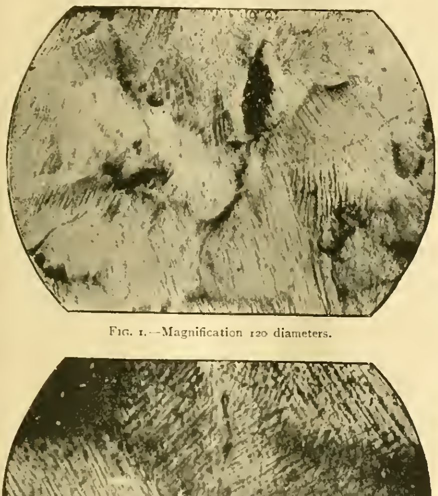

FIG. 1.—Magnification 120 diameters.

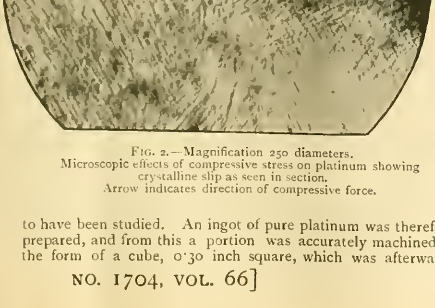

FIG. 2.—Magnification 250 diameters.
Microscopic effects of compressive stress on platinum showing crystalline slip as seen in section.
Arrow indicates direction of compressive force.

to have been studied. An ingot of pure platinum was therefore prepared, and from this a portion was accurately machined in the form of a cube, 0·30 inch square, which was afterwards carefully microscopically polished and then subjected to compressive stress in the testing machine.

Prior to the application of stress, and for comparative purposes, a polished face of the platinum cube was microscopically examined, but an even polished surface only was observed. A force producing a compression of 10 per cent. on the total height of the cube was then applied, and microscopic observations were taken at high magnifications of the effects of the stress on the microcrystalline structure of the platinum cube.

The polished side of the cube upon which the high-power microscopic examination was made was the one in line, or in parallel, with the direction of the compressive force.

Owing to the varied orientation of the different crystals in the mass of the platinum, the lines of cleavage as indicated by the minute "slip bands," were often seen at varied angles to the line of the straining force.

The general appearance of the disintegration of the large or primary crystal grains, produced by the pressure, on the pure platinum cube, was the apparent breaking up of the crystalline structure of the metallic mass, as seen in section, roughly diagonally to the line of the compressive force. The area enclosed by the main lines of disruption roughly approximating to the size of the large primary crystal grains.

The distances between the extremely fine lines, or "slip bands," appeared roughly to coincide proportionately with the size of the secondary or most minute crystals forming the mass, the finer "slip bands" appearing to indicate the crystalline slip which had taken place along the facets of the smaller or secondary crystals. The direction, however, of the main lines of the crystalline disruption did not appear always to coincide with the intercrystalline facet junctions of the large or primary crystal grains. The lines of least resistance, or greatest crystalline slip, seemed chiefly to develop at an approximate angle of about 45 degrees to the pressure line, as previously mentioned; but the line of greatest weakness in the mass structure of the metal was not always at that angle with the line of the disruptive force.

The authors hope that these experiments may prove of use in affording an indication of the comparative behaviour of the noblest metal platinum, with the behaviour of the constructive metals, copper, nickel, iron and steel, when under the influence of stress; and the experiments have also shown that the microscopic influences of stress in the heavy metal platinum are analogous to those which have been observed in metals of lower specific gravity.

June 5.—"Contributions to the Study of Flicker." Paper ii. By T. C. Porter, M.A., Eton. Communicated by Lord Rayleigh, F.R.S.

This paper is the sequel to that already published in the *Proceedings*, vol. lxiii. It first details various precautions which experiments, carried out since that paper, have shown to be necessary in estimating the rate at which a black disc with a white sector must be rotated in order that the sensation of flicker may just vanish. Results are given which prove that the central portion of the retina is less sensitive to flicker than its outer region. The effect on the flicker of the measured want of blackness in the black sector is also discussed. The most important results of a long series of experiments, in which many observers took part (in order to eliminate as far as possible the personal equation), is to prove that, if n be the number of rotations per second of the disc when flicker just vanishes, the angular magnitude of the white sector being kept constant, but the illumination of the disc being varied, by altering its distance from a measured and constant illuminant, then $n = a + b \log I$, where a is a constant, and b is also a constant for all illuminations between a very feeble one and one under which the disc becomes almost unbearably bright. A full description of the illuminants used and of the measurement of the illuminations caused by them on the disc is given in the paper. At very low illuminations it is proved that the value of b changes with unexpected rapidity, apparently becoming again constant. The bearing of the above equation on the practical value of the flicker photometer, and also the number of kinematograph photographs which must be projected on a screen per second in order to get rid of flicker, is stated.

The second important result is the experimental determination of n, when the illumination of the disc is kept constant, but its apparent brightness is altered by altering the angular magnitude of the white sector. If this last, measured in degrees, is called w, the magnitude of the black sector will be $360 - w$, and if

c and d are constants, then the relation connecting these quantities with n is $n = c + d \log w (360 - w)$. If the distance of the disc from the illuminant is now varied, so that I varies, the equation connecting all these quantities with n (the number of rotations of the disc per second when flicker just vanishes) is $n = k + k' \log I. \log w(360 - w)$, where k and k' are constants (though it must be remembered that k' has a different value for very feeble illuminations). All these results are clearly exhibited in the paper by numerous interesting curves. It is also shown that the different curves obtained by placing the disc in the different colours of the same spectrum, and varying the angle of the white sector by steps of 10° from 0° to 180° in each colour, can all be obtained by viewing the disc illuminated by *white* light and simply varying the intensity of the illumination, which proves that n is unaffected by the wave frequency of the different colours and is solely influenced by their intensity.

Finally a curve, showing the relative intensity of the light of different parts of the same spectrum, deduced from the results of the present paper, is given, and proves to be actually coincident, within the errors of experiment (except for the very faint illuminations at the two ends of the visible spectrum) with the curve expressing the same thing given by Vierordt, but obtained by him, as by Abney and others, in an altogether different way.

"The Spectra of Potassium, Rubidium and Cæsium, and their Mutual Relations." By Hugh Ramage, B.A., St. John's College, Cambridge. Communicated by Prof. G. D. Liveing, F.R.S.

Tables of the oxyhydrogen flame spectra of the above three metals are given, which contain a number of lines not hitherto recorded. The lines which form the second subordinate series of cæsium and several members of the corresponding series of rubidium are new; so also are some of the lines of the first subordinate and the principal series of both metals. The flame spectra were photographed with a spectrometer fitted with a Rowland plane grating; spark spectra of iron, titanium, &c., were superimposed on the flame spectra to furnish fiducial lines. Some of the lines in the red region of the spectrum were measured by eye observations.

Diagrams of the subordinate series in the spectra were drawn to scales of oscillation frequencies for abscissæ and (1) atomic masses, (2) squares of atomic masses for ordinates. The conclusions deduced in the author's previous paper (*Roy. Soc. Proc.*, vol. lxx. p. 1, 1902) from less complete data were amply confirmed. There is undoubtedly a very close connection between these series and the atomic masses, and the lines which connect the corresponding members of homologous doublets in diagram (2) do intersect on the ordinate of zero atomic mass. The points which bisect the limits towards which the subordinate series converge in each spectrum lie on straight lines in diagram (1). The constants in Rydberg's general formula were then expressed in terms of the atomic masses; the oscillation frequencies of the lines, calculated from the modified formula, are given in the paper, together with the observed numbers. The convergence points of the series were calculated by different methods and the results are given. It would appear from these that the two subordinate series do not converge towards the same limits.

All the strong lines and nearly all the weak lines which have been observed in the flame and arc spectra of these three metals are included in the three harmonic series. The differences between the corresponding series in the spectra appear to depend on the atomic masses alone. Reasons are also given for thinking that the principal and the second subordinate series are more closely related to each other than to the first subordinate series.

Chemical Society, June 5.—Dr. Thorpe, C.B., F.R.S., in the chair.—The action of ungerminated barley diastase on starch, part i., by Dr. J. L. Baker. The hydrolytic products of this action are a new amylodextrin and maltose. The former is slowly converted by the further action of the enzyme into maltose and a small proportion of dextrose. The decomposition of chlorates, part v., potassium chlorates in presence of oxides of manganese and the theory of perchlorate formation, by Mr. W. H. Sodeau. It is shown that, since the amount of chlorine produced by heating potassium chlorate in presence of manganese dioxide is not increased by reduction of pressure, no secondary reaction can occur, and therefore McLeod's theory of permanganate formation is untenable.—Studies in the tetrahydronaphthalene series, i., the diazo-amino-compounds of *ar*-tetrahydro-β-naphthalene, by Mr. C. Smith.—Experiments on phosphorus tetroxide, by Mr. C. A. West. When phosphorous oxide, P_4O_6, is heated at 300°, it decomposes into phosphorus tetroxide and free phosphorus. The former is an extremely stable substance, volatilising only with difficulty at 1400°. Its composition is represented by the formula P_8O_{16}. The decomposition of compounds of selenium and tellurium by moulds and its influence on the biological test for arsenic, by Dr. Rosenheim. Certain moulds, such as *Aspergillus*, *Mucor* and *Penicillium*, decompose tellurium and selenium compounds with the production of a fæcal odour which masks the garlic odour given off by these moulds when grown in arsenical solutions.—Constituents of gambier and acacia catechus, by Messrs. A. G. Perkin and E. Yoshitake. The authors have isolated from these sources three closely related substances, distinguished as catechins *a*, *b* and *c*.—The decomposition of oxalacetic hydrazone in aqueous and acid solutions, and a new method of determining the concentration of hydrogen ions in solution, by Messrs. H. O. Jones and O. W. Richardson. When the hydrazone is heated in aqueous solution it decomposes into pyruvic hydrazone and pyrazolone carboxylic acid, the production rate of the former being proportional to the concentration of the original hydrazone, and of the latter to the concentration both of the hydrazone and the hydrogen ions.—The dissociation constants of oxalacetic acid and its hydrazone, by Messrs. H. O. Jones and O. W. Richardson.—Derivatives of butyrylpyruvic acid, by Dr. A. Lapworth and Mr. A. C. O. Hann.—Sulphocampholene carboxylic acid, by Mr. A. W. Harvey and Dr. Lapworth.—Some properties of camphorquinonephenylhydrazone, by Dr. A. Lapworth and Mr. A. C. O. Hann. The authors have been unable to obtain the "keto" form of this substance in a pure state, but have obtained evidence of its existence and have studied the rate at which equilibrium between the "keto" and "enol" forms is attained under various conditions.—Optically active esters of β-ketonic and β-aldehydic acids, part i., menthyl hydroxymethylenephenylacetate, by Dr. Lapworth and Mr. A. C. O. Hann. The authors propose to investigate these esters in the hope of obtaining an insight into the peculiar tautomeric relations of the acids from which they are derived.—Part ii., menthyl acetoacetate, by Dr. Lapworth and Mr. A. C. O. Hann.—The mechanism of simple desmotropic change, by Dr. Lapworth and Mr. A. C. O. Hann. An extension of Brühl's views on the mechanism of tautomeric change.—Trimethylbrazilone, by Dr. W. H. Perkin, jun. An investigation is being made into the constitution of this substance, which is obtained by the oxidation of brazilin.

Entomological Society, June 4.—The Rev. Canon Fowler, president, in the chair.—Mr. H. W. Shepheard-Walwyn exhibited a male specimen of *Lampides baeticus* taken recently emerged at Winchester in September, 1899, and two varieties of *Lycaena icarus*.—Mr. C. P. Pickett exhibited one asymmetrical male and two females of *Dilina tiliae*, and a series of the same insect showing great variation in colouring and markings, bred during May, 1902.—Mr. F. Merrifield exhibited photographs showing the protective resemblances of the larva and pupa of *Hygrochroa syringaria*.—Prof. E. B. Poulton exhibited a lantern slide showing the perfect protective resemblance of *Hybernia leucophaearia* to the oak trunk upon which it rested.—Mr. A. Bacot exhibited hybrid larvæ resulting from a pairing between a male *Malacosoma neustria* and a female *M. castrensis*, also larvæ of *M. neustria* and reputed larvæ of *M. franconica* for comparison.—Mr. H. C. Elwes read a paper on the butterflies of Chile, illustrated with many specimens taken during an expedition last winter to that country. The poverty of the Chilian rhopalocerous fauna is notable. Of the insects represented there was probably only one really Chilian Colias, the most numerous family being the Satyridæ, of which some twenty-five species were taken. The Nymphalidæ are few in number, while three native Theclids and three Lycænids represent their respective groups. Mr. Elwes drew especial attention to one unique species, *Argyrophorus argenteus*, which flies at 3000 to 7000 feet, the upper-side of all the wings in male and female being unicolorous and brilliant metallic silver, the under-side resembling somewhat that of the Holarctic family Œneis. A similarly beautiful golden sheen was observable on *Cyclopides puelmae*, a species of Hesperid, but on the ground of protective coloration there seemed nothing in the surroundings of either insect to account for the peculiarity. Between alpine and lowland species there was no distinction,

although the season on the coast would be over when that upon the high mountains commenced.—Mr. S. L. Hinde read a paper, illustrated by lantern slides, upon the protective resemblance to flowers borne by an African Homopterous insect, *Flata nigrocincta*, Walker. He said that "the cluster of insects grouped to resemble a flower spike," which forms the frontispiece of Prof. J. W. Gregory's "Great Rift Valley," had attracted some criticism, and that as he was familiar with the insect figured, and with its larva, in a wild state, it seemed desirable to publish the evidence. In the plate the insects are collected on the vertical stem, the green individuals uppermost considerably smaller than the red ones beneath, like the unopened green buds towards the top of a flowering spike as compared with the expanded blossoms below. The separate representations of the green and red forms, however, indicate no difference in size, and experience confirms this conclusion, so that the impression conveyed by the frontispiece plate is erroneous. After further noting that the uniform deep pink colour of the exposed parts of the insects figured was also incorrect, Mr. Hinde remarked that he had never seen the insects grouped according to their colours, but invariably mixed, that he had never found larvæ and imagines on the same stem or even together on the same tree or bush, nor did the imagines affect vertical stems, but always those actually or approximately horizontal. Sir George Hampson said the insects figured were orange when brought home, and the pink-winged imago was an error of the colorist.

Mineralogical Society, June 10.—Dr. Hugo Müller, president, in the chair.—Dr. A. Hutchinson gave an account of the experiments he had made in order to discover the cause of the discrepancy in the results obtained by Meigen and Panebianco in the application of Meigen's method of discriminating calcite and aragonite. He found that calcite, when treated with a boiling dilute solution of cobalt nitrate, only remains white or becomes yellow (as stated by Meigen) when the cobalt nitrate contains traces of iron, and that Panebianco's lavender-blue colour is only obtained when the cobalt nitrate is free from iron.—Mr. G. F. Herbert Smith discussed some crystals of krennerite from Nagyag on which he found a large number of forms not previously recorded. He further exhibited the new three-circle goniometer recently constructed from his designs by Messrs. Troughton and Simms for the British Museum. He pointed out the advantages of the gnomonic projection in crystallography, and showed a table which he had prepared to facilitate the employment of this method of projection.—Mr. G. T. Prior exhibited specimens and described the mineral constituents of the volcanic dust which fell in Barbados on May 7 and 8 after the eruption of the Soufrière of St. Vincent. The fact that the constituents are like those of a hypersthene-augite-andesite connects the eruptions with the Pacific rather than with the Atlantic volcanic chain.—Mr. L. J. Spencer pointed out reasons for the non-existence of "kalgoorlite" and "coolgardite" as mineral species. At Kalgoorlie, in Western Australia, with the tellurides of gold and silver, sylvanite ($(Au,Ag)Te_2$), calaverite ($(Au,Ag)Te_2$), and petzite ($(Ag,Au)_2Te$), is frequently associated the telluride of mercury, coloradoite. The iron-black petzite and coloradoite are identical in external appearance, and sometimes occur intimately associated together. In such cases minute fragments detached from an apparently homogeneous mass are found on blowpipe analysis to be sometimes coloradoite and sometimes petzite. Analysis of larger pieces would therefore show the presence of tellurium, gold, silver and mercury in variable proportions, as is actually the case in the analysis of "kalgoorlite" and "coolgardite," described as new mineral species by Pittman in 1897 and by Carnot in 1901 respectively. Neither of these investigators appears to have been aware of the occurrence of coloradoite at Kalgoorlie, and the materials they analysed were without doubt mechanical mixtures of coloradoite and the above-mentioned tellurides of gold and silver, especially petzite.—Mr. R. H. Solly described the crystallographic characters of liveingite, a new sulph-arsenite of lead ($5PbS.4As_2S_3$) from the Binnenthal, a preliminary account of which was given by him in the *Proc. Cambridge Phil. Soc.*, 1901, xi. p. 239. Measurements of three good crystals more recently obtained, showed that the system was orthorhombic, and that $100, 110 = 44° 49'$; $010, 011 = 46° 48'$; $001, 101 = 43° 23'$. In the prism zone the faces (210), (430), (540), and in the macrodome zone the faces (302), (504), (908), (101) are well developed, and (100) is a cleavage plane. A pyramid zone with numerous small faces is also present. The crystals often exhibit a polysynthetic growth parallel to (100). In appearance they resemble rathite.

Mathematical Society, June 12.—Dr. E. W. Hobson, president, in the chair.—The president announced that the council had awarded the De Morgan medal, 1902, to Prof. A. G. Greenhill.—Prof. Love communicated a paper by Prof. Conway on Huygens' principle in a uniaxial crystal. It is shown that, when electric waves are propagated in a crystalline medium with an axis of symmetry, the radiation is resolvable into constituents (1) with electric force at right angles to the axis, (2) with magnetic force at right angles to the axis, (3) with both forces at right angles to the axis. The types of radiation that are due to electric and magnetic doublets with their axes parallel and perpendicular to the axis of symmetry are determined, and it is shown that the radiation received at any point can be regarded as made up of secondary waves due to such doublets distributed upon an arbitrary surface separating the point from the actual sources of the radiation.—Lieut.-Colonel Cunningham gave an account of some investigations on repetition of the sum-factor operation. The result of the repetition of the operation upon a number is very frequently unity when the operation is repeated sufficiently often; in the case of one small class of numbers the result is a perfect number; in another small class, a pair of amicable numbers; in a third small class, the result may increase beyond the power of practical calculation.—The following papers were communicated from the chair:—M. E. Picard, Sur un théorème fondamental dans la théorie des équations différentielles. This note deals with the question of the possibility of the existence of a non-holomorphic integral, which, besides satisfying a given ordinary differential equation, also satisfies a special condition at a certain point.—Mr. G. H. Hardy, some arithmetical theorems. Cauchy's theory of residues is used to obtain various relations between sums of terms of the form $\left(\left(\frac{\sigma b}{a}\right)\right)$, in which a and b are fixed integers, and σ is an integer which ranges over a certain set of values, the summation is taken with respect to σ, and $((x))$ denotes the algebraic difference between x and the absolutely nearest integer.—Prof. M. J. M. Hill, on a geometrical proposition connected with the continuation of power series. A power series with a circle of convergence C_1 having been derived from a given power series with a circle of convergence C_0, it is possible to choose successive positions of a point x, so that every point of the region that is common to C_0 and C_1 shall be within one at least of the circles described with x as centre to touch C_0 and C_1 internally.—Mr. J. H. Grace, on types of perpetuants. The numbers of perpetuants of one or more forms have been determined by Stroh and MacMahon, and the latter has accounted for each perpetuant by a corresponding umbral form. In the present paper the perpetuants of any number of forms are found by the direct reduction of Aronhold's symbolical forms.

Royal Meteorological Society, June 18.—Mr. R. Inwards, vice-president, in the chair.—Mr. F. C. Bayard read a paper on English climatology, 1891–1900, which is a discussion of the climatological data printed in the "Meteorological Record." In 1874, the Royal Meteorological Society commenced the organisation of a series of stations at which the observations are made twice a day on a uniform plan, so that the results may be strictly comparable with each other. In addition to these the Society in 1880 organised another class of stations, termed "climatological," at which the observations are made once a day, viz. at 9 a.m. Mr. Bayard on a former occasion worked up the results from these climatological stations for the ten years 1881–90, and in the present paper he gives the averages from sixty-nine stations for the ten years 1891–1900. The elements dealt with are temperature, relative humidity, amount of cloud, rainfall and rainy days, and the results are a valuable contribution to the climatology of the British Isles.—A paper by Mr. W. L. Dallas on earth temperature observations recorded in Upper India was also read, in which the author discussed the observations made on the temperature of the soil at three stations, viz. Lahore, the capital of the Punjab; Dehra Dun, in the north-west of the North-Western Provinces; and Jaipur, the capital of the native State of that name. The observations, which were made at depths varying from 4 inches to $45\frac{1}{2}$ feet below the surface, extended from 1884 to 1899.

PARIS.

Academy of Sciences, June 16.—M. Bouquet de la Grye in the chair.—On anomalous dispersion in correlation with the absorbing power of bodies for radiations of a determined period, by M. J. Boussinesq.—Arsenic as a normal constituent of animals, and its localisation especially in their ectodermic organs, by M. Armand Gautier. Remarks on a note of M. Gabriel Bertrand, and replies to the criticisms of Hödlmoser, Cerny and Ziemke. The author points out that his positive results for certain parts of the body were always accompanied by parallel experiments with the same reagents upon other portions of the body in which negative results were obtained. The fact that under proper conditions arsenic is only normally found in the skin, nails, thymus and thyroid gland is of the highest importance in toxicological researches. Stress is laid upon the attention to detail necessary to secure trustworthy results.—Dissociation of the elements of the energy expenditure of motors employed in overcoming frictional resistances, by M. A. Chauveau.—On the mode of multiplication of Trypanosomes in fishes, by MM. A. Laveran and F. Mesnil. *Trypanosoma Remaki* and *Trypanoplasma Borreli* both multiply by binary division similarly to *Tr. Brucei* previously described. A fish carrying these parasites can easily inoculate another of the same species. The parasites do not appear to have any pathogenic action on the fish.—On a hypothesis concerning the origin of satellites, by M. L. Picart. A consideration of the question as to the possibility of small planets or comets being converted into satellites of a larger planet. None of the satellites of the known planets correspond to the conditions necessary for this view.—On certain couples of applicable surfaces, by M. Maurice Fouché.—On the integration of differential systems which are completely integrable, by M. E. Cartan.—On the displacement and disturbance of equilibrium, by M. Jouguet.—The electric discharge in flame, by M. Jules Semenov.—On the electrostatic effects of a magnetic variation, by M. V. Crémieu. In reply to the criticisms of M. Carvallo, the author describes the latest form of apparatus used by him. Although, according to the Maxwell theory, the effects produced should have been quite appreciable, the results have been uniformly negative. The conclusions arrived at in the earlier work of the author on the non-existence of electric forces created in dielectrics by magnetic variations are completely confirmed by the later work.—On a magnetic disturbance observed at Athens on May 8, by M. D. Eginitis. The magnetic disturbance coincided with the eruption of Mont Pelée. From the fact that the seismograph showed absolutely no disturbance, and that a similar phenomenon was simultaneously observed at Paris, it is concluded that the disturbance must have been of a magnetic or electric nature.—The polymerisation and heat of formation of oxide of zinc, by M. de Forcrand. On ignition, zinc oxide undergoes a change into a polymeric modification with the evolution of heat.—Combinations of hydrogen sulphide with anhydrous aluminium chloride, by M. E. Baud. By the action of liquid sulphuretted hydrogen upon anhydrous chloride of aluminium, two compounds are formed, one, $Al_2Cl_6.H_2S$, stable at the ordinary temperature, the other, $Al_2Cl_6.2H_2S$, dissociable at about $-45°$ C.—On the alloys of cadmium and magnesium, by M. O. Boudouard. Two definite alloys of these two metals have been isolated, $CdMg$ and $CdMg_4$. The study of the fusibility curves pointed to the existence of a third, $CdMg_{30}$, but this could not be definitely isolated.—On the existence of arsenic in the organism, by M. Gabriel Bertrand. The author has elaborated the method of M. Gautier for the determination of minute quantities of arsenic in organic material, and is able to detect with certainty as little as 1/1000th of a milligram. The results of M. Gautier are generally confirmed. A point of especial interest was the proof of arsenic in the thyroid glands of *Phoca barbata*, captured near Spitzbergen, a case to which the theory of industrial contamination could not possibly be applied.—On isomerism in the benzylidene-methones and on the preparation of an α-methyl-α-isopropyladipic acid identical with dihydrocamphoric acid, by M. G. Martine. The identity of the acid obtained by the oxidation of benzylidene-menthone with potassium permanganate with the dihydrocamphoric acid of Crossley and Perkin has been completely proved.—Pyromucic and isopyromucic acids. The action of phosphoryl chloride and phophorus pentachloride, by M. G. Chavanne. Isopyromucic acid differs from the isomeric pyromucic acid in not being a true acid, and is apparently a phenol.—On a new glucoside, aucubine, extracted from the seeds of *Aucuba japonica*, by MM. Em. Bourquelot and H. Hérissey. The new glucoside occurs in the seeds mixed with a large quantity of cane sugar, from which it can be separated by fermentation of the sugar by yeast. Dextrose is one of the products of hydrolysis of the glucoside.—On the production of glycose by the muscles, by MM. Cadéac and Maignon. The muscles resemble the liver in producing sugar after death, the amount produced being a function of the temperature to which the muscle is exposed. This action is in no way connected with putrefaction.—On the hæmolytic action of cobra poison, by M. A. Calmette.—Permanent contraction in the pigeon, by M. Louis Boutan.—On the aerobic fermentation of manure, by M. C. Dupont. The aerobic fermentation of farm manure is due to two bacteria, *Bacillus mesentericus ruber* and *Bacillus thermophilus Grignoni*; these bacteria burn the nitrogenous materials, sugars, starches and gums.—On the internal morphology of the genus Thylacoplethus, a parasite of the Alpheidæ, by M. H. Coutière.—On the impressions produced under the influence of certain gases, by M. A. J. J. Vandevelde. The author has produced images similar to those described by MM. Vignon and Colson, making use for this purpose of hydrogen sulphide, ammonia, hydrochloric acid and iodine.—On the subterranean river of Trépail, Marne, by M. E. A. Martel.—Physiological photometry, by M. G. M. Stanoiévitch.—A new method of measuring muscular sensibility, by MM. Toulouse and Vaschide.—On a vertical series of densities of sea water of the Mediterranean, by M. J. Thoulet.

THURSDAY, JULY 3, 1902.

THE NEW INTERNATIONAL CATALOGUE.

The International Catalogue of Scientific Literature. M. Botany, part i. (Published for the International Council by the Royal Society of London, 1902.)

WHEN the idea of a complete index of scientific literature was first seriously put forward, it was thought by not a few persons that the magnitude of the task would prove of so overwhelming a nature that its promoters seemed to be courting almost certain failure.

The older "Catalogue of Scientific Papers" published by the Royal Society, although of considerable value, cannot in any sense be called a complete record of the hordes of papers which were pouring forth in ever-increasing volume from the pens of useful and useless writers alike. Moreover, the publication of this catalogue has been in abeyance since 1883.

It is obvious to anyone reflecting on the matter that it was no longer possible for any single scientific society, unless extraordinary funds were placed at its disposal, adequately to continue the work. For apart from the cost of actual production, the catalogue itself, unless rapidly brought up to date by the publication of complete bibliographies at short intervals, must inevitably lose much of its value to those actively engaged in work. And thus on grounds of convenience and utility, as well as of policy, it was decided that endeavours should be made to place the undertaking on an international basis. A considerable number of leading foreign societies and individuals were approached with the view of ascertaining the possibility of evolving a satisfactory scheme which should at the same time be a practicable one. On the whole the replies were so favourable that it became a plain duty to push forward an enterprise from which, if successful, would accrue results of inestimable value to science and hence of immense importance to the world at large.

A conference was held in London during the summer of 1896, and it was attended by representatives of more than twenty different countries. At that meeting the preliminary steps were taken towards the inauguration of a catalogue of which the volume before us comes as the first instalment. A committee of the Royal Society appointed to investigate the working details of the scheme reported to a second representative conference in the autumn of 1898, and at this meeting the general lines on which the work was to proceed were drawn up. A subsequent international conference was held in 1900 to consider the more detailed schemes which had been drafted as the coordinated results of very extensive inquiries and investigations by the Royal Society. Furthermore, inasmuch as in a costly undertaking of this nature financial as well as other kinds of cooperation forms an essential factor of success, this aspect of the matter also received the full consideration of the delegates, and a satisfactory conclusion was arrived at.

As a result of the deliberations, the Royal Society agreed to act as the publishers of the catalogue and to advance the initial capital required, on the understanding that the latter be repaid during the ensuing five years. The ultimate control of the whole undertaking is vested in an international council, a convention of which is to be held in London in 1905 and thenceforth at ten-yearly intervals. It has been also agreed, and very wisely, that the scheme of the catalogue as now finally approved is to be given a fair trial of at least five years' duration before any serious modification may be introduced.

The first convention was held in December 1900, when it was resolved that the work should begin forthwith and that the contents of the catalogue should be compiled as from January 1, 1901. It is, however, satisfactory to know that the gap existing between the catalogue of 1800-1883 and that of 1901 now incepted is about to be filled up, and that a list of papers published during this interval, together with a subject-index for the whole period, is in actual course of preparation.

Much of what has here been said will doubtless be already familiar to many readers of NATURE. But only those who have watched the untiring activity of the leaders of this enterprise who have thereby succeeded in doing so much for the organisation of science, can at all adequately estimate the continuous strain and effort required to cause it to take a tangible shape.

As at present determined, the main branches of science are treated separately and are arranged under seventeen heads, each being indicated by a letter of the alphabet. The further ramifications of each branch are grouped according to authors and subjects. The classification of the latter (printed in English, French, German and Italian) is based on convenient subdivisions of the particular science concerned, and the respective headings are denoted, for purposes of index and cross-reference, by numbers. The final units are also arranged in alphabetical order.

The first volume of the catalogue which has just made its appearance deals with the literature of botany, and it is stated to be a first instalment of the entire volume due for the year 1901, and it is promised that a second part shall be forthcoming in the near future. As soon as the difficulties inseparable from the commencement of such a work have been overcome, it is intended that an entire volume shall be published in each year. We venture to think that it might have been well to have waited in the present instance until the volume could have been completed, or else that part i. should have been confined to the literature of a stated portion of the year.

The appearance on the title-page of Mr. Daydon Jackson's name is of itself a guarantee as to the care with which the compilation has been effected. The slips actually detected are few, but we confess that we have not been able to ascertain on what principle some of the omissions are to be accounted for. Thus, to take the case of the *Annals of Botany*, there appeared in the June and September issues two papers, both by M. C. Ferguson, dealing with the reproduction processes in pines, and yet, so far as we can discover, only the second one is quoted. We have also noted other omissions from the *Annals*, to confine ourselves to the case of one periodical alone.

Nevertheless, making due allowance for anomalies which experience will soon correct, the volume deserves

the highest praise, for it possesses in a large degree just those qualities that one specially seeks in a work of this nature—qualities that will render it an indispensable addition to the library of every serious student of botany. Papers that have appeared in comparatively inaccessible or little-known periodicals are duly recorded in their places, whilst owing to the clearness of the main subdivisions and the excellence of the system of cross-reference, it is usually easy to search out all the literature cognate to any given subject.

The translation of titles originally printed in unfamiliar languages is a useful feature that this volume will share with those dealing with other branches of science.

Another character of special utility lies in the enumeration, under their appropriate subject-headings, of the new genera and species that have been published during the period covered by the volume. It is sincerely to be hoped that it will always be found practicable to continue to give such *complete* lists, although their preparation must necessarily involve no small amount of labour.

It remains to be said that the typographical arrangements are clear and good, and the few printer's errors on which we have lighted are so trifling as to be almost negligible. Those who have been concerned in its production are to be congratulated on the appearance of this, the first instalment of a great work the value and importance of which it would be impossible to overrate.

J. B. FARMER.

THE GEOMETRY OF COG-WHEELS.

La Costruzione degli Ingranaggi. By Prof. D. Tessari Pp. xvi+226; with eight lithographed plates. (Turin: Fratelli Bocca, 1902.)

THE study of the proper forms to assign to the teeth of cog-wheels in order that they may run smoothly affords such simple and useful illustrations of the principles of geometry of roulettes that it seems a pity that few mathematical students have time to interest themselves in the mattter. In regard to the assertion of certain empiricists that even if the teeth are not constructed on mathematical principles they will adjust themselves in the course of wear, it is pointed out that an immense amount of power will be wasted in wearing the wheels down, and instead of the teeth becoming adjusted they will run loose.

Whatever form be assigned to the profile of the teeth of one wheel, it is possible to construct a suitable profile for the teeth of the second wheel, and the two profiles are said to be *conjugate.* The condition that two profiles may be conjugate is that they must both be roulettes traced by the same rolling curve on the so-called "primitive" circles of the two wheels. If, however, a number of wheels are to be mutually interchangeable, the profiles of any two must be conjugate, and it is necessary that the generating rolling curve or "epicycle" should be the same for every wheel, and the most convenient form is the so-called epi-hypocycloidal form, in which the portion of the profile outside the primitive circle is an epicycloid and that inside the primitive circle a hypocycloid.

An inferior limit to the number of teeth is determined by the condition that contact between one pair must not cease until contact has taken place between the succeeding pair, and for smooth running it is further desirable for at least two pairs of teeth to be simultaneously in contact. To make the number of teeth a minimum, it is necessary to make the generating "epicycle" as large as possible, in which case the hypocycloidal form becomes a straight line; and it is shown by a diagram that the minimum number of teeth possible is nine for a pair of equal wheels, or six for a rack and pinion arrangement.

Now if the teeth are cut radially down to the base, the narrowness of the base is a source of weakness, especially when the number of teeth is small and their height consequently considerable; moreover, wheels of different sizes constructed in this way are not interchangeable. For such reasons as these another form is frequently adopted in which the profile is an involute of a circle, which is in this case of smaller radius than the primitive circle and is called the "base circle."

We are next introduced to another form of gearing, in which the teeth of one wheel are replaced by circular cylindrical spindles, an arrangement which, by the way, was some years ago tried in the gearing of tricycles for the purpose of reducing friction, and is still illustrated by chain wheels. In this case the conjugate profile is a curve parallel to an epicycloid, or in the case of interior cogs, a parallel to a hypocycloid. A particular case is that in which the ratio of angular velocities is as 1 to 2, when the spindles on the smaller wheel may be reduced to three or even two in number, and these work in rectilinear slots, an arrangement familiar in connection with the so-called "oval chuck" and the "trammel" methods for describing ellipses.

Hitherto the teeth considered have been of cylindrical form, with axes parallel to those of the wheels. We are now led to consider wheels with spiral teeth, an arrangement due originally to Hooke and White, and which is well illustrated by the diagonal rack and pinion coarse adjustment of the modern microscope. This arrangement has been supposed by some writers to eliminate nearly or quite all friction. Prof. Tessari, however, considers that this view is due to an erroneous opinion as to the nature of the contact existing between the surfaces, and, moreover, that further investigation from an experimental standpoint is desirable on the subject of whether any saving of friction is effected by helicoidal cogs as against cylindrical ones. Here is an important subject for researches which might well be carried out in a modern laboratory of experimental mechanics.

In the eighth chapter a new subject is introduced, namely, gears for converting uniform into variable angular velocity, and the first point is the determination of the primitive lines of wheels adapted for the required purpose. In other words, we have to find the form of two perfectly rough curves which by rolling on each other about parallel axes will effect the required transformation. If we assume that the angular coordinates of the two wheels are θ and θ', and h is the distance apart of the axes, the polar equations of the primitive lines for any given relation between θ and θ' are determined from the equations $r + r' = h$ and $r d\theta = r' d\theta'$. Among the possible arrangements we note a pair of ellipses rotating about their foci, and combinations of elliptic, parabolic or hyperbolic arcs, also arcs of equiangular spirals; many of these arrangements are illustrated by elegant

diagrams. The arrangement here called the "Maltese cross," in which the driving wheel moves the following wheel through a given angle once in every revolution, is interesting in connection with machines for counting revolutions. When a pair of conjugate primitive curves have been constructed, the form of the teeth is determined by the condition that in order to be conjugate they must be roulettes traced on the primitives by the same rolling curve.

From wheels rotating about parallel axes, Prof. Tessari passes on to bevelled cog-wheels, giving both uniform and variable ratios of velocities, and finally to the case where the shafts of the driving and following wheels are neither parallel nor concurrent, but are disposed in any positions in space. A simple application is the well-known modification in which the cogs on the driving shaft are replaced by a spiral thread.

While the present work contains no difficult mathematical formulæ, it places the theory of cog-wheels on a perfectly rigorous and logical basis, and the exposition appears remarkably simple and lucid. There are two lessons to be learnt from the perusal of such a book by those who will learn them. The "practical man" has to learn that a study of the why and wherefore of such matters as the shape of cog-wheels is not very difficult, and will help him a great deal more than merely learning up empirical rules. The mathematician, on the other hand, should see that if he will only make his knowledge of the geometry of conics, equiangular spirals, epicycloids and other curves sufficiently accessible to the practical man he will be doing good work, and by such means as this he may succeed in stimulating a much greater demand for his abilities than exists at present. Here we have a subject for the proper understanding of which a connected knowledge of certain geometrical facts is indispensable. But the average mathematician is somewhat apt to discourage the learner from acquiring a mere connected knowledge of facts; in the early stages by the importance he attaches to the performance of what we may call the scales and five-finger exercises of mathematics, and in the later stages by the stress he lays on the solution in the examination room of questions the meaning of which is often difficult even for a skilled mathematician to interpret when reading the paper at his leisure. Consequently, when the student of applied mechanics wants to learn about epicycloids and hypocycloids for the purposes of better understanding such a book as the present, there is great fear that he may not, as he certainly ought, employ the services of the mathematician.

G. H. B.

EVOLUTION AND DESIGN.

The Lesson of Evolution. By Frederick Wollaston Hutton, F.R.S., Curator of the Museum, Christchurch, New Zealand. Pp. 100. (London: Duckworth and Co., 1902.) Price 2s.

OF the two essays composing this little book, the first formed the inaugural address to the Australian Association for the Advancement of Science at the Hobart meeting in January, 1902. Part of the second essay formed the presidential address to the Geological Section of the same Association at the Sydney meeting in 1898, while the second part of this essay, dealing with "Later Life on the Earth," has been written for the present work. The second essay may be at once dismissed with the remark that it is a tolerably well-digested statement of the facts of biological evolution as revealed by palæontological succession. The first essay, which embodies the "lesson" which the author desires to impress upon a wider public than the audience assembled to hear the address at Hobart, is the one which claims the most critical attention, because the author most unhesitatingly and boldly declares that he has discovered the aim and object of evolution—that the purpose for which this process was designed and set going on this earth is "the development of man's moral nature."

In order to appreciate Captain Hutton's position, it may be as well to state at once that he is a thorough evolutionist. He begins from the very beginning of the process, and devotes some pages to the subject of inorganic evolution, in the course of which he advocates the meteoritic origin of the solar and other systems as expounded by Lockyer and supported by Prof. G. H. Darwin. The motive powers of evolution are gravitation (Newton), the dissipation of energy (Kelvin), and selection (Darwin). But granting all this and accepting to the full extent the teachings of modern science so far as concerns the mechanism of the process, there has hitherto been no attempt outside the theistic pulpit to introduce the doctrine of special design into the philosophy of evolution to the same intimate degree that is attempted in the present work. It is not going too far to say that we have here the ancient teleology, which Huxley used to declare had been killed by the establishment of the doctrine of evolution, revived and amended in terms of evolution. The author's views are anthropocentric in the extreme. Not only is the development of man's moral nature the goal towards which evolution is directed, but every step in the process has been regulated so as to lead to this end. Thus with respect to the distribution of the metals:—

"Also if man was ever to become civilised, gold, copper and other metals in accessible positions were necessary, although they are of no use in the economy of animals and plants. Gold, however, would be almost useless to man if it was abundant, while iron would be equally useless if it was as rare as gold. But we know that these, as well as the other substances, exist in their right proportions" (pp. 24–25).

"We have therefore in the composition, size and position of the earth overwhelming evidence of design. And as we can prove that carbon existed in the Archæan era before life appeared, and that gold, iron and copper existed long before man, we must also allow that the results of evolution had been foreseen and provided for" (p. 27).

If we ask further why this admirable distribution of the metals has been necessitated, we find in a note (p. 25) that it is because gold is the most suitable metal for coinage, copper and iron for weapons. It would perhaps be unkind to inquire further why, after the right proportions had been provided for, the subsequent distribution of one of these metals had been left to take care of itself, as judged by the extraordinary disparity in the quantities possessed by individual members of that most highly civilised human community for which the original

distribution was planned! Also it is rather a matter of surprise that the author should not have made use of the opportunity of pointing out how the sponges and organisms of the Cretaceous seas had been endowed with the power of accumulating silica so that when man was evolved he might find flints ready to hand for the purpose of making his weapons. This suggestion is offered for a future edition.

Speaking frankly, and with all respect for Captain Hutton's beliefs and his perfectly honest and straightforward attempt to square them with the teachings of the modern doctrine of evolution, we cannot admit that the new teleology as thus presented is in any way preferable to the old teleology of the Bridgwater Treatise school. It leads us by a very circuitous track into precisely the same *cul de sac* into which the authors of those famous volumes led us. The argument in favour of design, for example, as drawn from the distribution of the metals, is very suggestive of the well-known story of the providential location of towns so as always to be on the banks of rivers!

In order to avoid misapprehension, let it be stated here that the author's position *may be* perfectly sound. There is nothing in the doctrine of evolution in the abstract which antecedently excludes the possibility of the whole process being the result of design. In calling attention to this point the present work may be regarded as useful. But there is much more of faith than of reasoning in the pages before us, and where belief is substituted for scientific argument—as is the case, for example, in the treatment of the immortality of the "spiritual" part of man (p. 45)—we are afraid that Captain Hutton's address will fall flat upon the world of science. The work which shall bring the doctrine of evolution into absolute harmony with the theory of design in nature has yet to be written.

R. Meldola.

A NEW TEXT-BOOK OF PHYSICAL CHEMISTRY.

The Elements of Physical Chemistry. By Harry C. Jones. Pp. xi + 565. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1902.) Price 17*s.* net.

THIS very readable book differs in many respects from recent text-books treating of physical chemistry; it resembles more closely a modern version of Lothar Meyer's treatise, but contains, at the same time, the more recent views, the introduction of which dates from van 't Hoff's memorable paper in 1887. It is non-mathematical; indeed, the treatment of the subject might have often been more methodical and clear if symbols had been more freely employed.

Beginning with Dalton's laws, Avogadro's hypothesis, and Dulong and Petit's law, methods of determining atomic and molecular weights are briefly described; too briefly, indeed, unless the student studies the original memoirs, to which copious reference is made in the foot-notes. A general sketch of the periodic arrangement of the elements follows, and some pages are devoted to J. J. Thomson's, to Lord Kelvin's and to Clerk Maxwell's deductions regarding the magnitude and structure of molecules. The normal gas-laws are next treated of, with the deviations, explicable on the theory of dissociation. After some pages on the kinetic theory of gases, their specific heats are dealt with. Passing on to the spectra of gases, a sketch of Balmer's law is given, and, as usual, reference to some of the most recent literature is appended in the foot-notes.

The liquefaction of gases forms the next section, but here some of the facts stated are incorrect; they will doubtless be rectified in a second edition. This gives a natural transition to van der Waals's theory, and the well-known form of the Andrews diagram suggested by the late Prof. James Thomson is reproduced. It is a pity that this diagram, which shows curves greatly differing in form from those calculable by van der Waals's equation, or from those representing deductions from direct measurement, should have ingrained itself in all text-books.

Kopp's classical researches on the boiling points of liquids are next considered; but Walker's later researches, in which the boiling points of the members of certain homologous series are connected by a simple expression, find no mention. Again, while Rowland's results bearing on the specific heat of water at different temperatures are alluded to, those of Griffiths are omitted.

The next section is devoted to the refractive indices of liquids and their rotatory powers. But here the matter is too condensed; in many cases the important points are merely touched, and a beginner would find it difficult, without much fuller explanation, to form correct views regarding the subjects treated.

The same fault must be found with Prof. Jones's synopsis of Kopp's work on molecular volumes; it is really impossible in a single page to give any idea of the nature of the problem to be attacked, the method of attacking it, and the results obtained. On the other hand, methods of determining molecular weights of liquids by their capillary rise receive five pages, although here, too, the arrangement of matter might have been improved.

In all, 165 pages are devoted to what may be termed the older aspects of physical chemistry, and the rest of the book, comprising 383 pages, deals with the more modern developments of the subject, solutions, thermochemistry, electrochemistry, photochemistry, and finally chemical dynamics and equilibrium.

There are a good many inaccuracies in the work; it would have been considerably improved by careful revision. For example, on p. 223, where a proof is given of the relation between osmotic pressure and lowering of freezing point, the symbol M stands for both molecular weight of solvent and of dissolved substance, and p has two meanings—percentage composition and pressure. Such oversights are very apt to confuse the mind of a beginner.

The writer's style is, on the whole, clear; but throughout the work there are careless expressions. For example, "heat is either evolved or *consumed*." Such *lapsus calami* will doubtless, however, be corrected in subsequent editions.

The reviewer's verdict is that the author has, on the whole, given a fairly comprehensive and reasonably exact sketch of the modern aspects of physical chemistry in a

comparatively small number of pages. The book gives a better bird's-eye view of the whole subject than most recent works, and it has the great advantage that copious references make it possible for the student to consult the literature of the subject and supplement from original sources any lacunæ in Prof. Jones's presentation of facts and theories. W. R.

OUR BOOK SHELF.

Other Worlds. By Garrett P. Serviss. Pp. xv + 282. (London: Hirschfeld Bros., Ltd., 1902.) Price 6*s.* net.

WHO amongst us has not, at some time or other, considered the question of the possibility or probability of the habitability of the planets that pass across the face of our sky, and wondered whether any of these worlds is an "earth" with all her attendant phenomena? A very excellent account of our neighbours from this point of view will be found in the book before us, which, although it hails from the other side of the Atlantic, yet will nevertheless be welcomed, as it comes from the land where the most recent and very valuable work on the observations of the surface markings of the planets has been done. As has often been pointed out, it is not the large telescope that is necessary for planetary observation, but clear and still air, a comparatively small telescope, and an intelligent eye. In Arequipa the Americans have such a condition of atmosphere, and it is there that important observations of some of the planets have been made.

In the present volume the author gives the reader a very clear insight into the present condition, so far as can be gathered from observation, of each of the planets, and the information is conveyed in such an enticing manner that the book should be interesting reading to everyone. Besides being accurate, the contents are well up to date, as shown by references to Pickering's work on the observations, and deductions from them, of the lunar surface.

The concluding chapter gives a brief but sufficient account of the means of finding and recognising the planets when they are visible in the sky, and in this is included a set of charts of the zodiacal constellations to facilitate the work of a beginner.

Numerous well-reproduced illustrations, many from photographs and drawings made at the Lick Observatory, accompany the text, and the frontispiece shows the Martian surface as charted by Schiaparelli.

As a popular exposition of the degree of habitability of the planets the book is to be recommended, and the clear large print adds to the comfort of the reader.

The Basis of Social Relations. By D. G. Brinton. Pp. xvi + 204. (London: John Murray, 1902.) Price 8*s.* net.

The Criterion of Scientific Truth. By G. Shann. Pp. 51. (London: Cassell and Co., Ltd., 1902.) Price 1*s.* 6*d.*

THE persons responsible for the publication of the posthumous work of Dr. Brinton, described above, would have done better if they had taken a more comprehensive view of their editorial duties. As we are told in the preface, no attempt has been made at verifying references; so that we have highly debatable statements constantly made on such vague general authorisation as "Plato," "Wundt," "Quetelet," "an American scientist," and so forth. Curious inaccuracies in matters of fact have likewise been allowed to stand in various places, *e.g.* at p. 44, where we read that Crete was the source of "Greek law" (whatever that vague expression may mean), and a well-known citation from the famous Hymn of Cleanthes, occurring in the "Acts of the Apostles," is said to be from "a Cretan poet," and at p. 13, where it is asserted of Jevons's "logical machine" that it "worked as well as the human brain," the truth being, as all logicians know, that that ingenious invention requires all but the purely mechanical part of the inferential process to be performed for it by the operator.

Some of these statements would possibly have been removed by the author had he lived to give the book his final revision, but others are such as could hardly have been made by a writer really acquainted with many of the subjects upon which Dr. Brinton expressed himself with confidence. No serious student of ancient history would subscribe to the assertion that the early Romans were dominated *exclusively* by the lust of conquest, or the Greeks by the love of art (p. 111), nor does a study of the erotic poetry of the Christian Middle Ages lend much support to the notion that "chivalry" was the expression of profound respect for woman as a sex, and devotion to a high ideal of monogamy (p. 173).

As a whole, the book is somewhat disappointing. It is rather a series of *obiter dicta* on the conditions of social development than a connected study. It is hard to understand the author's exact conception of the "ethnic mind." Sometimes (*e.g.* p. 25) we are told that the "group" is a "generic concept" with no "objective existence," yet again (*e.g.* p. 28) that its "actual existence" cannot be denied, and that it is related to the individual mind as the building to its component stones. Dr. Brinton held very strong opinions on some subjects of current controversy. He was, for instance, confident that monogamy was not primitive in the species, and again, that "acquired characters" are transmissible. It is a pity he—or his representatives—should have seen fit to abstain from all citation of evidence or references in dealing with such important questions.

Mr. Shann's little work is a pleasantly written and fairly thoughtful essay in support of the view which sees in scientific truth simply a set of convenient descriptive hypotheses. The "criterion" of truth he adopts is the simplicity and adequacy with which our formulæ enable us to picture a connected train of sensational experiences. Hence he lays great stress upon two points; the origin of all knowledge must be sensational, and no knowledge can be absolute or final. From the standpoint adopted he discusses various cases of the supersession of inadequate by more adequate scientific formulæ intelligently and readably, but he seems not to have realised the grounds on which many able thinkers would dissent from the empirical phenomenalism he advocates. Has he ever asked himself whether his general philosophical theories would enable him to give a reasonable account of mathematical truth? If he will reflect, for instance, on the nature of number, and the difficulties involved in the assumptions that numerical truths are of sensational origin and only relative validity, he will probably discover that there are serious gaps in the phenomenalist theory of knowledge which he advocates. There is no doubt that he has something on this point to learn from Kant, whom he does not mention at all in his historical synopsis, and possibly even more from Plato, whom he dismisses with a sentence or two of vague generality.

A. E. T.

Opere matematiche di Francesco Brioschi. Pp. 416. (Milano: Ulrico Hoepli, 1901.)

THERE could not have been a more fitting tribute to the memory of Francesco Brioschi than the publication of his collected papers in quarto form. In order to carry out such an undertaking, a committee was formed shortly after his death consisting of Profs. G. Ascoli, E. Beltrami, G. Colombo, L. Cremona, G. Negri and

G. Schiaparelli, and the result is a work of which the present is the first volume. It contains fifty-four of Brioschi's papers, of which forty were originally published during the period 1851–1857 in the *Annali di Scienze matematiche e fisiche* under the editorship of Barnaba Tortolini, and the remainder appeared in the *Annali di matematica pura ed applicata*, which formed a continuation of the previous journal, during the years 1858–1861. The last of the series is Brioschi's classical monograph on the theory of covariants and invariants of binary forms and their principal applications. The arrangement adopted has thus been to classify Brioschi's papers according to the journals in which they are published and not according to date or subject-matter.

The committee placed the principal work of editing the volumes in the hands of Profs. Beltrami and Cremona, and on the death of the former the task was continued by Prof. Valentino Cerruti, the papers in the present volume being revised in addition by Profs. Pascal, Gerbaldi, Loria, Pittarelli, Reina and Tonelli. To these names must be added those of Profs. Bianchi and Capelli in connection with the revision of material for succeeding volumes.

A photogravure portrait of Brioschi forms a frontispiece, and a short history of his life will appear at the end of the complete work, forming a lasting monument to the great Italian mathematician.

Webster's International Dictionary of the English Language. To which is now added a Supplement of 25,000 Words and Phrases. Edited by W. T. Harris, Ph.D., LL.D., Editor-in-Chief. (London: George Bell and Sons.) Price 2 guineas net.

NO more convincing proof of the extent to which the English language has been enriched as a result of the wonderful activity in scientific circles during recent years could be found than this new edition of the world-renowned "Webster." The supplement, which distinguishes this from the last edition of the dictionary, is largely composed of scientific terms and technical expressions which have come into existence during the last decade. It is only necessary to glance down a list of the names of the men of science who have assisted Dr. Harris in the preparation of this substantial addendum to satisfy oneself that the definitions will prove clear, accurate and complete. Repeated tests have shown that such anticipations are well founded, a conclusion that will not seem surprising when it is stated that among the assistants on whose services the Editor-in-Chief has been able to rely are such scientific experts as Prof. E. S. Dana, Prof. G. K. Gilbert, Dr. E. S. Holden, Dr. T. C. Mendenhall, Prof. E. L. Nichols, Prof. I. Remsen, Prof. A. E. Verrill, Prof. L. F. Ward, and many others of equal authority. The dictionary will continue to merit the confidence with which it has long been regarded.

Education and Empire. Addresses on certain Topics of the Day. By Richard Burdon Haldane, M.P., LL.D., K.C. Pp. xvi + 195. (London: John Murray). Price 5*s.* net.

IN the first two addresses in this volume Mr. Haldane is concerned entirely with educational problems, and in both of them pleads in a convincing manner for more earnest attention to the great need of increased facilities for higher technical instruction and for scientific research in this country. The comparisons which are here instituted between what is done in the United Kingdom and in Germany and the United States of North America in the matter of providing technical colleges and laboratories for scientific research should, if anything will, explain to our manufacturers and merchants the reason for the phenomenal success of our trade rivals.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Mr. Marconi's Results in Day and Night Wireless Telegraphy.

I CAN assure Prof. Joly that his explanation (p. 199) will not do.

The observed effect, which if confirmed is very interesting, seems to me to be due to the conductivity, and consequent partial opacity, of air, under the influence of ultra-violet solar radiation.

No doubt electrons must be given off from matter (dust as well as other matter) in the solar beams; and the presence of these will convert the atmosphere into a feeble conductor. Conducting power in the sea-water surface assists and guides the waves, retaining them in two dimensions after the same fashion as a telegraph wire retains them in one; but conductivity in the dielectric itself will tend to dissipate and enfeeble the waves, by a process of reflection resulting in some amount of distortion. OLIVER LODGE.

June 27.

Kinetic Theory of Planetary Atmospheres.

IN the *Astrophysical Journal* for November, 1901, is printed a paper of mine in the first part of which a method is proposed for determining the mean temperatures of the atmospheres of the planets and those of their surfaces. In the second part of the paper an attempt was made with the use of these temperatures to determine the composition of the atmospheres of the planets by the "empiric" method proposed by Dr. Johnstone Stoney and based on the supposition that helium escapes from the earth's atmosphere. The most probable velocity of the molecules of helium is 1093 metres per second at 15° C. (the mean temperature of the earth's surface), and the velocity sufficient to overcome the earth's attraction is 11,170 metres per second. Hence it has been inferred that a gas escapes from the surface of the planet, if the most probable velocity of its molecules is 10·22 times less than that required to overcome the planet's attraction.

Prof. G. H. Bryan (NATURE, No. 1698, p. 54) has remarked that according to his and Mr. Cook's calculations, founded on the kinetic theory of gases, helium cannot escape to any sensible extent from the earth's atmosphere by the motion of its molecules among themselves. But the assumption that helium cannot be retained by the earth's attraction is arbitrary. It is possible that helium exists in our atmosphere in only a very small quantity, because it is contained in the interplanetary medium in very insignificant proportions; its escaping, if it occurs, is effected, perhaps, by ordinary diffusion. We know several substances, as thorium, osmium, &c., which are very rare minerals, though their atomic weight is great. It is possible, moreover, that even hydrogen can be retained by the earth; it seems to be confirmed by the observations of M. Gautier (*Bulletin* de la Soc. chim. de Paris, December 5, 1900, p. 884) and Lord Rayleigh (*Phil. Mag.*, vol. iii., pp. 416–422, 1902), who have found free hydrogen in atmospheric air.

Assuming the last supposition, we must substitute for the number 10·22 some other less than 7·42 ($=\frac{11170}{1505}$, where 1505 is the most probable molecular velocity of hydrogen at 15° C.), for instance, 7, 6, or 5, in order that an appreciable number of molecules may attain the speed sufficient to carry them to infinity; and consequently table iii. in my paper must be changed correspondingly. E. ROGOVSKY.

The Coloured Sunsets.

THE recent fine weather has enabled one to observe the sunsets and after-glows under very favourable circumstances, and the most striking feature observed was the predominance of the beautiful salmon-colour tinge, which became most intense when the after-glow was brightest.

Practically none of the sunsets observed were strikingly red,

but the yellow, purple and pinkish tinges were most general. The sunsets of the 22nd and 26th and the sunrises of the 27th, 28th and 29th were those which showed the salmon tint to the greatest advantage.

In a letter to NATURE of last week, Mr. Krohn recorded some remarkable sunsets at Madeira, while a *Daily Mail* correspondent at Bombay (June 29) writes:—"The extraordinary red sunsets which have been witnessed for several days past are believed to be due to Martinique dust in the upper atmosphere."

There is little doubt, therefore, that the dust is on the move, being carried by the upper air currents, and perhaps we may yet observe more brilliant effects.

WILLIAM J. S. LOCKYER.

Solar Physics Observatory, June 30.

As one of the first, in your pages, to call attention to the import of the sunset glows in 1883, I have additional interest in noting the recurrence of similar glows during the past few days. On three nights, at least, they have been more marked than any seen by me since the eighties.

I observed the glow first on June 26, at Croydon, but it was noted at Street, Somerset, on the 24th (Tuesday last). I was there from the 27th to 29th, and saw glows each evening. On the 27th it was brighter, though less widely spread, than at Croydon on the 26th. But at Street, on the 26th, I am informed by my cousin, Mr. Joseph Clark, that it was brighter than on the 27th.

The following resemblances to the glows in 1883 may be noted:—

(*a*) The distinct interval between the sunset itself, with illuminated lower clouds, and the glow. The latter began 20 to 30 minutes after sunset.

(*b*) The detachment from the horizon.

(*c*) The shade, pink, ranging from salmon tinges (26th, due perhaps to London smoke-haze) to almost purple.

(*d*) The clear interval between a "glow" and "after-glow" about half an hour after sunset (noted on 28th and 29th).

(*e*) The "after-glow" growing as brilliant as the glow. Indeed, on the 29th it was more brilliant, and alone attracted attention from the ordinary observer.

(*f*) The strong and prolonged "counter glow" above the earth-shadow (specially noted on 28th, up to 8.50, or half an hour after sunset).

(*g*) The prolonged ruddiness along the horizon, signs still remaining on 29th at 11 o'clock.

On June 26 (Croydon) the glow arose to at least 75°; otherwise 55° or so was the extreme limit. So far the pink glows have not been observed later than about 9.10, or, say, 50 minutes after sunset. In brilliancy they cannot compare with those of 1883, but perhaps with the glows two years later.

June 30. J. EDMUND CLARK.

The Halos of May 1, 8 and 22.

SINCE the publication in NATURE of the letters on these three phenomena, my attention has been directed by Prof. S. P. Thompson to the "Memoire sur les Halos," by M. A. Bravais. The first of the above three halos, recorded by Prof. E. E. Barnard, is apparently new, unless the radius of one of the two circles was in reality considerably smaller than that of the other; if this was the case (which from the account seems scarcely likely) this halo might be part of the halo depicted on Plate iii. Fig. 98, and described on pp. 87, 88 and following, and of which Bravais says that the different parts are by no means always visible together.

There is no doubt that the halo described by me is substantially the same as that depicted on Plate iii. Fig. 101, though it will be seen that mine has a cusp not previously described, whilst one of the mock suns given by Bravais is altogether wanting.

Lastly, the halo described by Prof. Grenville A. J. Cole will be found in the same work (Plate iii. Fig. 101), where it is interesting to note that only one parhelion is drawn, and that is the one given by Prof. Cole on the left of the horizontal diameter of the smaller circle. T. C. PORTER.

Eton, Bucks, June 30.

Matter and Motion in Space.

MR. WILLIAM STANLEY, an American philosopher and engineer, said a few days ago that the grandest words ever uttered by any man on this planet were spoken by Lord Kelvin when he said that if all the matter in the universe were reduced to its ultimate atoms and equally divided through all space, the disturbance caused by the beating of the wing of one mosquito would bring about everything that we find in the material universe to-day. I have written to Lord Kelvin asking him where I can find some account of this, but he denies that he ever said anything of the kind. However, as Mr. Stanley declares that it appeared in NATURE, perhaps you can put me in the way of getting a copy of the paper which contains this remarkable utterance, which, by the way, is quite true, and if Lord Kelvin did not say it, I only have to say that he might well have been the author. HIRAM S. MAXIM.

18 Queen's Gate Place, London, S.W., June 25.

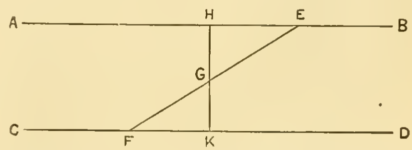
A Method of Treating Parallels.

MAY I venture to suggest through your columns a method of dealing with the theory of parallels which seems to me to possess some advantages?

Since a philosophically rigid proof of their properties may be regarded as out of the question in the present state of our knowledge, the only desideratum in laying the foundation of this important section of geometry is an axiom the truth of which shall be apparent to the mind of a beginner.

I propose that the following should be adopted, as being the property of parallels which is most prominent in matters of ordinary life, and hence to those who have not made a special study of geometry the most obvious:—"A straight line which is perpendicular to one of two parallel straight lines is perpendicular to the other."

The more general property, that parallels are equally inclined to any straight line which cuts them, follows immediately:—



Let AB and CD be two parallels met by a third line at E and F. Bisect EF at G, and draw GH perpendicular to AB and produce HG to meet CD at K. Then HK is perpendicular to AB and CD.

Then in the two triangles GEH, GFK,

angle EHG = FKG (right angles),
angle EGH = FGK (I. 15),
EG = GF (construction).
∴ HEG = KFG (I. 26).

Hartley College, Southampton. S. W. RICHARDSON.

THE FIRST FRUITS OF THE GERMAN ANTARCTIC EXPEDITION.

THE protracted voyage of the *Gauss* from the Elbe to Cape Town excited some anxiety at the time, and called forth a few comments unfavourable to the sailing power of the ship. It appears, however, that the delay was due mainly to the fact that many days were spent in carrying on oceanographical and magnetic work, although the change of programme which led to the abandonment of a visit to Ascension shows that the duration of the passage did to some extent exceed anticipations. The *Gauss*, we may recall, left the Elbe on August 15, 1901, passed the Lizard on the 20th, called at St. Vincent in the Cape Verde Islands on September 11, and reached Cape Town on November 23. The work done in various branches of science was discussed in a preliminary manner on board, and an account of it was issued in March in a paper of

108 pages, with numerous maps and diagrams, by the new Oceanographical Institute in Berlin and the Geographical Institute of the University of Berlin, under the direction of the head of both institutions, Baron F. von Richthofen.[1] The work, though mainly of value in the instruction it afforded the workers, still constitutes a contribution to our knowledge of the Atlantic, and promises well for the scientific harvest which we hope the *Gauss* has by this time begun to reap in less known waters.

The memoir consists of four parts—a general report of the expedition by the leader, Prof. E. von Drygalski, seven reports on the scientific work by the various specialists on board, technical reports by the chief engineer and the captain of the ship, and finally a special report on the establishment of the auxiliary station at Kerguelen.

As the investigators on the *Discovery* brought themselves into working order by monographing the island of South Trinidad, those on the *Gauss* set about the general description of St. Vincent in the Cape Verde group as their first exercise. Dr. Emil Werth describes the topography and types of vegetation of the island, and Dr. Philippi gives a brief account of the geology. The island is described as an ancient volcano, the central plain corresponding to the crater, the rim of which survives in parts as a peripheral mountain-chain.

The more systematic work of the expedition commences with Prof. von Drygalski's report on the oceanographical observations which were his special care. As far as the equator these were confined to the surface, but from the equator southwards deep-sea observations were added at regular intervals, along the course which lay alternately a little to the west and a little to the east of the meridian of 20° E. The superficial conditions are very ingeniously shown by means of curves drawn on the map of the route, the abscissæ being the projection of the track on the meridian and the ordinates the values of temperature, salinity and density *in situ*. The surface temperature, closely following that of the air, rose steadily from 17° C. at the mouth of the English Channel to an average of 27° in the Doldrums (16° N. to 5° N.), then fell to 24° at the equator and remained steady to 15° S., after which it fell steadily, reaching 18° C. in 30° S. The salinity curve showed maxima in the tropics both north and south, separated by a minimum in the belt of calms at 7° N. The density of surface-water *in situ* remained constant between the temperate zone and the tropics in both hemispheres, but fell to a single minimum in the equatorial belt of calms, where the maximum temperature met the minimum salinity. Samples for the determination of density and chlorine were collected every four hours and a number of different methods were employed for making the determinations. Titrations of chlorine were controlled by Knudsen's standard samples of sea-water, which were supplied to the expedition for the purpose. In addition to two patterns of direct-reading hydrometers, a set of Nansen's total-immersion hydrometers by the use of which the troublesome factor of surface-tension is eliminated were utilised, and a refractometer was also employed for the optical determination of the density of the sea-water. The value of the salinity deduced by Knudsen's tables from the chlorine determinations was always found a little lower than when deduced from hydrometer or refractometer observations; the mean error of the determinations was found to be least for titration of chlorine and greatest for the refractometer. The chief difficulty with regard to that instrument was found to be the temperature correction; but Prof. v. Drygalski points out the very decided advantage of the immersion refractometer with which the *Gauss* is provided over the differential refractometer formerly used.

[1] Bericht über die wissenschaftlichen Arbeiten auf der Fahrt von Kiel bis Kapstadt und die Errichtung der Kerguelen Station.

The colour of the sea-water was systematically observed, but the range of Forel's xanthometer being found insufficient, the more extensive scale of colours used by Luksch on the *Pola* expedition was adopted instead.

Deep-sea soundings were made with a modified Sigsbee machine. Using a detaching weight of 35 kilogrammes as a sinker, soundings were completed in 5000 metres (2770 fathoms) in seventy minutes in calm weather. Prof. v. Drygalski found the Negretti and Zambra reversing thermometer unsatisfactory for deep soundings, on account of the shaking of mercury out of the inverted bulb in hauling up through the hot tropical surface-water. The Miller-Casella thermometers, on the other hand, acted admirably, and he regretted not having taken a larger supply. We think, however, that in the very different conditions of the polar seas this opinion of the relative utility of the two types of instrument will very likely be reversed.

On the voyage between 37° N. and 34° S. no fewer than thirty successful deep-sea soundings were taken, of which nine gave depths exceeding 5000 metres (2770 fathoms), and the deepest as much as 7230 metres (3950 fathoms). The positions of the soundings were chosen so as to throw light on special problems of suboceanic configuration.

Opportunity was taken to test the Pettersson-Nansen insulating water-bottle in these depths, and the result was to show that the great contrast of temperature between the bottom and surface in the tropical seas was too much for the power of insulation, and that the inner cylinder of water altered its temperature somewhat before a reading could be made. This difficulty will, of course, not be experienced in the more uniform temperatures of polar seas.

An interesting fact brought out by the determination of salinity as well as temperature at each point of observation was that about the depth of 800 metres, where the sudden change in the temperature curve occurs between the warm upper and the cold lower waters, there occurs an actual inversion of the salinity curve, showing that a stratum of minimum salinity is interposed between the two salter layers.

The study of oceanic deposits brought out some new facts, and suggests problems not very easy of solution. By using sounding tubes of 2 or 3 centimetres diameter and 200 centimetres long some very long cores were obtained. One of these, from the depth of 7230 metres (3950 fathoms), in 0° 11′ S., 18° 15′ W., showed distinct stratification. The core was 46 centimetres long; the uppermost 13 centimetres consisted of red clay containing numerous fragments of volcanic rock, then followed in order four bands of different colour, passing from brownish-grey to dark and then light grey. The dark grey layer distinctly resembled a terrigenous deposit, and the light grey layer, the lowest of all, was the only one containing a perceptible proportion of calcium carbonate. The bearing of this observation on past changes in the configuration of the ocean and the distribution of land is pointed out. A still more curious specimen was a core 69 centimetres (say 2 feet) long, obtained in 35° 52′ S., 13° 8′ E., from a depth of 4957 metres (2750 fathoms). The uppermost 11 centimetres consisted of a brown clayey quartz sand with very little volcanic or calcareous material, while the next 12 centimetres were almost pure globigerina ooze with fragments of the upper layer, and the greater mass of the section consisted of material similar to the upper layer, but with the clayey material predominating over the sand. Dr. Philippi could not account for this appearance of sand in a pelagic deposit by considerations of the prevailing wind (which blows towards, not from, the South African deserts), or by currents, so he is driven to suggest that the material is ice-borne, though he acknowledges the

difficulty of icebergs in sufficient numbers reaching so low a latitude.

The biological work was very fully developed on the voyage, and in addition to a close watch being kept on the changes in the surface plankton by continuous tow-netting, attention was devoted to the use of very large wide-meshed nets (one was of 7 metres diameter) for horizontal towing, and to a vertical net of 2 metres diameter. A somewhat unexpected result of the latter was the discovery that very young fishes increased in number with the depth. Thus in a vertical draught from 500 metres twelve "fischchen" were found, in one from 800 metres fifteen, from 1000 metres thirty-two, from 1200 metres thirty-six, from 2000 metres forty-three and from 3000 metres no fewer than ninety-six. Most of them belonged to the genus Cyclothone.

Dr. Bidlingmaier enters very fully into the methods and difficulties of magnetic work at sea. The two principal instruments in use are a Bamberg's deviation magnetometer and a Lloyd-Creak inclination instrument identical with that supplied to the *Discovery*. The results are not yet ready for publication, but a number of observations were made both at the ports of call and at sea. At Cape Town Profs. Beattie and Morrison repeated the comparison of their own instruments with those of the expedition which they had made a short time previously with the *Discovery's*, thus enabling a comparison of the instruments of the two exploring vessels to be made.

The report concludes with a letter from the auxiliary station at Kerguelen which was established by Herr Enzensperger on the shores of Royal Sound in November, and was visited by the *Gauss* on her way southward in January, 1902; but the letter had been dispatched some weeks before the ship arrived.

We miss any detailed account of the meteorological work of the expedition, or particulars as to the placing and working of the various self-recording instruments on board.

It is impossible to overrate the importance of preliminary work in comparatively easy conditions before grappling with the manifold difficulties of the polar seas. Indeed, we believe that those who organise polar expeditions for scientific work would be well advised to insist on a preliminary trip of at least three months' duration before the final plans and equipment are settled. The result would not be waste of time; it would render fruitful a vast amount of work, which without preliminary experience is sure to be wasted. In this respect Antarctic expeditions are more advantageously situated than those to the Arctic regions, where the ship is in the midst of its field of work before the men have settled down to life on board and to work under the countless limitations which harass the man of science at sea.

H. R. M.

RURAL EDUCATION IN FRANCE.[1]

ONE is always being reminded afresh of the essential solidarity of the thought of civilised man; no movement seems to begin with one man or in one place; the tide rises, and though this or that first receives the impulse and takes credit for being the creator, yet the wave has already reached many a distant creek and inlet. In two or three years the idea of giving an agricultural colouring to the work of the rural elementary schools of England has been getting itself translated into codes and circulars and syllabuses; the Agricultural Education Committee gave the needful push, but if anything else were wanted to prove that it only supplied the "starter" to a medium already prepared to react, it would be a consideration of the work done in the same direction in France, as set out in the report before us. And the United States, our Australian Colonies and Canada, to name no more cases, would all report similarly—their educators have begun to realise that primary education has been systematised on bookish and artificial lines, which can nowhere be more pernicious or more easily avoided than in the purely country school, with trees and fields around it.

Unfortunately, the pioneers of any movement, just because they are pioneers and have brought a certain amount of original thought to the work, are apt to forget that there must be other people progressing on the same lines; they shut themselves up in their own schemes, and bit by bit work through the same mistakes which everyone else has previously made.

Here comes the special value of such reports as the one we are now considering, and had this account of the attempt in France to impart an agricultural bias to the rural primary school been available a year or two earlier, many experiments destined to failure might have been avoided, and much well-meant effort directed into more fruitful channels.

The problem in France is like that of England, there is the same depression in agriculture, the same dominance of the town in the organisation of the State, the same increasing distaste for a farming life—in a word, the same impossibility of the primitive industry, with its toil, its small returns, its isolation, competing either for men or capital with the specialised affairs of the town. But as Mr. Brereton reminds us, France is more of an agricultural country than we are, so the problem was taken in hand earlier there; the economic difficulties were palliated by protection, and the primary education of the country was overhauled to ensure that it should stimulate, rather than divert, the child's desire to live on the land

The volume before us consists of two reports; the first is a very detailed account by Mr. Cloudesley Brereton on the organisation of rural education in the Departments of Calvados, Orne, Sarthe, Indre et Loire, Loir et Cher. Here the machinery for the education both of child and teacher; the relations, financial and administrative, between the central authority, the department and the commune; the status of the teachers, the inspectorate, the departmental professors, &c., are set out at length, together with the personal impressions of the author while visiting typical schools in the district indicated. Mr. J. C. Medd, the author of the second report, deals with the country bordering Mr. Brereton's on the north and east; he is, perhaps, more specially concerned with "l'enseignment agricole" than with the general machinery of education. The first thing that strikes us is the predominance given in both reports, and indeed in the French system, to the programme. Most new movements in education narrowly escape being choked in their early days by a programme, and as we in England are still struggling to free ourselves from the wrappings of syllabuses, it is interesting to read how the vastness of the schemes framed by the departments in response to the law of 1879, resulted in practically no teaching except by a few enthusiasts. This was realised, and the Ministry issued in 1897 a well-reasoned scheme "on the teaching of elementary notions of agriculture in rural schools,"[1] which forms the basis of the work that is proceeding to-day. Even this circular seems to err in attempting instruction which is too definitely technical for the primary school, and so degenerates into text-book repetitions. The study of manures and artificial fertilisers has an extraordinary attraction for the sort of man who teaches in a primary school; he needs to be warned that they do not constitute the whole of agriculture, rather than encouraged to devote his "champs

[1] Vol. vii. of "Special Reports on Educational Subjects," published by the Board of Education.

[1] A translation appears in the Report of the Irish Commission on Primary Schools [c 8925].

d'expérience" and his pot cultures to demonstrating the effect of nitrogen, phosphoric acid, potash, &c. Whatever happens to this sort of teaching in England, we hope the primary school will be left uninvaded by theories of manuring. Practical farmers have sometimes denounced the whole race of agricultural teachers as advertising agents for the artificial manure makers, and if when they happen to visit the village school, they hear little lads of twelve and thirteen glibly reciting scraps about nitrates, kainit and the like, there will only be one strong prejudice the more against "education."

All the programmes set out by Mr. Brereton and Mr. Medd are based too much on chemistry, which in an elementary school is necessarily academic instruction, and too little on botany and zoology, which can be made real, and interwoven with the child's daily experience of field and garden. Nor is there any indication of work done by the children themselves; the instruction seems wholly didactic.

But after all a syllabus should only be regarded as a series of boundary walls; it should say, "do what you like within these limits, but don't think yourself called upon to do it all." It does harm when it becomes a stereotyped substitute for the teacher's judgment. On the teacher the whole thing depends, and this is thoroughly recognised in both reports. It is because the current generation of teachers is not prepared for the work, either in England or France, that the work of vitalising the instruction of the village school must proceed slowly. France has the advantage of a properly organised system of training colleges through which all their teachers pass, and in them a course of agriculture is given by the departmental professor. In Mr. Brereton's opinion he has so many more pressing duties that this part of his work is performed in a somewhat perfunctory fashion; the teaching is too academic, and not enough use is made of the garden for practical instruction. It is difficult to see the value of "a lot of hard digging" for students when the gardener is left with the more ticklish operations that follow. We do not gather that the training colleges have arrived at any conception of a "normal" course in these studies bearing on agriculture and horticulture, which would practice the teacher in the very experiments, indoors and out, that he will want to pass on to his scholars. No one is in more need of this kind of drilling, for the primary teacher's training is always disposing him to think that if he knows how to describe an experiment he knows how to do it. Mr. Medd found a teacher who was afraid to do experiments lest his boys should meet with accidents and he himself be involved in claims for compensation; and Mr. Brereton records how unsuccessful the manure experiments, either in the open or in plots, were apt to be, which indeed is only "pretty Fanny's way."

However it is clear that the crux of the whole problem, lies with the teacher. Turn him out with an adequate preparation, keep him encouraged on the right lines by the inspectorate, and let him work out his own salvation. Uniformity is the least of virtues in this matter; the spirit the teacher puts into the task alone tells, and his individuality ought to be reflected in the instruction he gives, until each school has a special character of its own.

We trust these reports will be widely circulated and widely read; they will show what can be done, and may save us from expecting too rapid a progress. Mr. Medd speaks, perhaps, with more knowledge of country life, more experience of the same kind of thing at home, even if his enthusiasm does lead him to see things rather as they are meant to be than as they are. Mr. Brereton has the keener pedagogic eye for the place where the organisation becomes paper only. But both reports are eminently readable. Mr. Brereton is not afraid of letting his own personality appear, and if the final homilies which he addresses to the farmer, parson and squire suggest that Mr. Brereton is young, and knows the country chiefly *en bicyclette*, those poor sinners are too chastened already to take his advice otherwise than with a smile.

A. D. H.

THE SMITHSONIAN INSTITUTION: ITS DOCUMENTARY HISTORY.[1]

THE Smithsonian Institution, the great scientific establishment at Washington, which, in many respects, is to the United States of America what the Royal Society is to this country, was founded under the will of James Smithson (b. 1765), a son of Hugh Smithson, afterwards Duke of Northumberland, by Elizabeth Macie, a cousin of the Percys. The story of how it came to be founded, and of its great work for the United States and for the world, has been more than once recounted in this Journal. An article contributed by the late Dr. G. Brown Goode (NATURE, vol. liii. pp. 257, 281) in January, 1896, contained a very full account of the origin of the Institution and of the system of its administration; and, when the same writer edited, under the auspices of the Institution itself, a work on the "History of its First Half-Century," we took occasion in reviewing it to give a comprehensive outline of the rise and progress of this great centre of scientific energy (NATURE, vol. lviii. p. 271).

The work at present under review does not perform the same function as that of Dr. Goode. It is not a history of the Smithsonian Institution, but, as the title-page declares, it is a collection of "documents relative to its origin and history." In fact, it brings down to date a volume with the same title which was published in 1879. In the latter volume the documents relative to the inception and organisation of "the Smithsonian" from 1835 to 1837 were printed, and the present volumes cover the whole period from 1835 to 1899.

In compiling and editing these documents, Mr. William Jones Rhees, the keeper of the archives of the Smithsonian Institution, has very admirably performed a most arduous task. A compiler is not called upon to produce a work of high literary art, but he is called upon to give with faithfulness and accuracy all that comes strictly within the scope of his compilation, and this Mr. Rhees appears to have done. He has given us two classes of documents: first, the will of James Smithson, with correspondence, &c., relative to the bequest, and, secondly, a full reprint of those congressional proceedings which contain legislation relative to the establishment of the Smithsonian Institution. The extraordinary minuteness of the information preserved in these documents, especially of the first class, is sometimes almost amusing. Not only have we the will of James Smithson and the documents in the Chancery suit brought by the U.S. Government against the British Government, but we have the lawyers' bill for costs of the suit and the full account of the expenses of Richard Rush, who came over to fetch the money. We not only have a list of the stocks transferred by decree of the High Court of Chancery and a schedule of the personal effects of James Smithson, but we have all the details of Smithson's tea-service—12 cups and saucers, 6 coffee cups, teapot, slop basin, sugar basin and lid, &c. Indeed, such a mass of material, important and unimportant, as is printed in these two volumes would be overwhelming were it not accompanied by a good index. But this, by the editor's care, has been given, and those who have had experience of biographical or historical authorship and who have sighed over the lack of particulars which so often belongs to the early stages of a history will not quarrel with a minuteness of detail

[1] "The Smithsonian Institution: Documents relative to its Origin and History, 1835–1899." Compiled and edited by William Jones Rhees. 2 vols. (Pp. liii. + 1044 and xvi. + 1045 to 1983.) (Washington, 1901.)

which is thus made readily available. Mr. Rhees's volumes will doubtless become for the future historian a storehouse of information great and small, and for the official a book of reference of permanent value.

In the voluminous reports of congressional proceedings which are here reprinted, many things will be found which are of special interest to English readers. There are numerous allusions to our own institutions, such as the Royal Society and the British Museum. Among other matters of the kind we note, in the proceedings of the thirty-third congress (1853-55), a letter of Prof. Agassiz, in which he mentions that Smithson's magnificent bequest of 105,000*l.* sterling was originally intended for our own Royal Society, but that certain scientific papers which that gentleman offered for publication in the *Philosophical Transactions* were declined, "upon which he changed his will and made his bequest to the United States." One can scarcely, however, grudge the loss to our own country in view of the liberal spirit and the enlightened policy which have always ruled the affairs of "the Smithsonian," and have done so much to advance the cause of science.

That policy has not been maintained without many a struggle. It took, to begin with, eight years to decide what form the establishment for "increase and diffusion of knowledge" was to take. Schemes for "a library, a botanical garden, an observatory, a chemical laboratory, a popular publishing house, a lecture lyceum, an art museum," all fought together and killed each other, and when this consummation was reached and the Smithsonian Institution was erected upon the battlefield, the ghosts of two at least of the old schemes—the library and the college—continued to haunt the proceedings of congress and cause endless trouble. It was in the course of one of these after-battles—a battle with those who desired to divert the funds of the Institution from scientific work to the foundation of a great library—that a letter from Prof. Benjamin Peirce was read which makes honourable mention of the scientific work both of the foundation and the founder, an extract from which may serve as an appropriate conclusion to this notice:—

"The valuable contributions to knowledge which have already been made by the Smithsonian Institution are a living proof that vast libraries are not necessary to the development of new thoughts. If you will compare these memoirs with the scientific productions of the same period in Europe you may find them, perchance, inferior in erudition, but not in profoundness and originality of thought. Do you believe that Smithson, who was himself engaged in chemical investigations, could have intended a library by his words 'an institution for the increase and diffusion of knowledge among men'? If you will examine his nine memoirs to the Royal Society, of which he was an active member, and his eighteen other contributions to science, you will not find one of them which required a library for its production. Each was the natural growth of a deeply thinking mind. Smithson was emphatically a maker, not a collector of books; and, in the scientific circle to which he belonged, the ordinary use of language would have totally precluded the interpretation which some men of quite a different cast of mind have presumed to impose upon his words" (p. 557).

H. R.

ARCTIC MAGNETIC OBSERVATIONS.

A SYSTEMATIC series of observations on terrestrial magnetism, atmospheric electricity and aurora was commenced by Prof. Birkeland and his assistants in 1899-1900, and a report upon some of the results was published last year.[1] The first observations were made at Bossekop (Finmarken), in the north of Norway. For magnetic observation, self-recording photographic apparatus was employed of the Eschenhagen pattern, the drums carrying the paper being capable of rotation at two speeds, the faster supplying a very open time scale. Fast runs were made simultaneously on certain prearranged days at Bossekop and Potsdam. A comparison of the records showed the simultaneous, or practically simultaneous, occurrence on several occasions of small regular magnetic waves at the two stations. Similar previous comparisons by Eschenhagen and others have led to similar results, but the comparatively great distance—some 2000 kilometres—between the two stations in the present case makes the results of special interest.

Only a portion of the report mentioned in the foot-note is devoted to the work at Bossekop. A considerable part is occupied with the description of experiments with electric discharges in vacuum tubes, in which Prof. Birkeland has succeeded in producing phenomena having a close resemblance to some of the more prominent features of aurora. Reference is also made to work by Prof. J. J. Thomson and other recent investigators in vacuum-tube discharges. There is also a discussion of the bearing of the observations and experiments on Prof. Birkeland's theory of the cause of aurora and magnetic storms. This he believes to be electric currents in the upper atmosphere, the ultimate source of which he ascribes to kathode rays or other electrical emanations from the sun. The observations and experiments are illustrated in the text and in various plates at the end of the book.

This work is to be regarded only as introductory to a larger scheme in which Prof. Birkeland is about to embark, and in which he desires the cooperation of magnetic and meteorological observatories. The further scheme is described in two circulars which have recently been widely distributed.

The Norwegian Government is to maintain four stations in operation from August 1, 1902, to June 30, 1903. They are situated at Bossekop and in Iceland, Spitzbergen and Nova Zembla. At each of the stations there will be continuous photographic registration of the horizontal and vertical components of magnetic force and of the declination. The instruments are of the latest Eschenhagen pattern, similar to those supplied to the German and British Antarctic expeditions, with arrangements for running at ordinary or at rapid rates. Rapid runs are to be made on certain specified days and times, mainly during the 'term' hours on the 1st and 15th of each month, according to the scheme agreed on between the British and German Antarctic expeditions.

In addition there are to be rapid runs from 9 to 11 p.m., G.M.T., on December 2 to 8, 1902, January 2 to 8 and February 3 to 9, 1903. Prof. Birkeland is anxious that as many magnetic observatories as possible should participate in this scheme of rapid registration. He also asks for the cooperation of meteorologists in observing cirrus clouds, and especially in recording the direction of cirrus bands when such exist. This information is more particularly desired during the days of special magnetic observations referred to above. Prof. Birkeland thinks it probable that high cirrus may be influenced by the electric currents which he believes to exist in the upper atmosphere, and to which, as already stated, he ascribes a principal, if not an exclusive, part in the production of aurora and magnetic disturbances.

One of the principal objects of having four stations in Arctic regions is to obtain data from which calculations can be made as to the direction, altitude and intensity of atmospheric electric currents, if such exist. Prof. Birkeland hopes to obtain quantitative results sufficiently definite to put his theory to the test. The completeness of the test will, however, be much enhanced by the

[1] "Expédition Norvégienne de 1899-1900 pour l'étude des aurores boréales. Résultats des recherches magnétiques." Par Kr. Birkeland. Pp. 80; with 12 plates. (Christiania, 1901.)

cooperation of existing magnetic observatories in Europe and other parts of the world.

As one of the principal desiderata is magnetic curves with very open time scale, it may not be out of place to explain that it is not necessary for this purpose to have a specially constructed magnetograph of the Eschenhagen or any similar pattern with small magnets. The ordinary Kew pattern magnetograph, with the usual damping arrangements, requires only a simple addition to the clock to work admirably as a rapid-motion instrument. Additions of this kind have been made to the Mauritius magnetograph by Mr. Claxton, the Director of the Royal Alfred Observatory, and a similar arrangement has been made at Kew itself at a trifling cost. The objection has, indeed, been raised to the use of ordinary magnetographs for this purpose, that the natural period of vibration of the magnets may coincide with that of the short magnetic waves which it is especially desired to investigate. When Eschenhagen described his early observations he apparently believed that the earth magnetic waves were restricted to one or two definite short periods, notably one of about thirty seconds; and he approved a short period of vibration for the magnet system so as to avoid possible synchronism. The records at Potsdam and Bossekop, however, discussed by Prof. Birkeland, and those taken elsewhere, show waves of all periods from eight or ten seconds up to several minutes, the longer-period waves being identical with those long familiar to all concerned with the records of the older types of magnetographs run at the ordinary slow rate. It would thus appear that synchronism is likely to happen very rarely, whatever type of magnetograph is employed. In some respects, of course, a very short period in the magnet system has its advantages, but it is not without its drawbacks. It means small magnets, entailing the use of small mirrors, and so necessitating a more intense light or more sensitive paper than is requisite when heavier magnet systems and larger mirrors are used. The greater robustness of the large-magnet systems is also a recommendation to those responsible for obtaining the records, especially at stations which do not possess a skilled mechanic and are not situated near large towns, a situation which the spread of electric tramways is fast rendering impossible.

C. CHREE.

CORONATION HONOURS TO MEN OF SCIENCE.

As we went to press last week, news of the King's serious illness was published, and national rejoicing at the anticipated Coronation ceremonies was suddenly changed to sorrow and deep anxiety. Since then, the nation has been slowly recovering from the shock, and the favourable bulletins which the King's physicians have issued this week encourage the hope that the crisis has been successfully passed and that His Majesty's convalescence is assured.

The operation for perityphlitis, from which the King has been suffering, was decided upon by Lord Lister, Sir Thomas Smith, Sir Francis Laking, Sir Thomas Barlow and Sir Frederick Treves, who are in attendance upon the Sovereign. It is beyond our province to describe the medical history of the illness or the nature of the operation performed by Sir Frederick Treves; but we are glad to know that scientific knowledge renders it possible to give relief to the sufferer without the fear of complications which made the surgeon's work almost hopeless before the introduction of antiseptic methods. Remembering this, we trust that the dark days have been passed and that progress towards recovery will be uninterrupted.

When the illness of the King became known, it was scarcely expected that the honours to be conferred in connection with the Coronation would be announced. But by His Majesty's express wish the list was published on Thursday last, and we give below the names of men of science included in it. The new Order of Merit which has been created by the King is of particular interest. We have applied to the Lord Chamberlain for a copy of the Warrant of the Order, but so far have not received one; the general principles upon which the Order is founded will, however, be gathered from the following information given to and by the *Times*:—

The new Order is clearly founded on the lines of the well-known Prussian "Ordre pour le Mérite." It will have the same comprehensive range and character, including, besides British subjects who have won conspicuous distinction in the naval and military services, those who are exceptionally eminent as men of letters and in the fields of art and science. The number of its members will be, as is right, very restricted. It is, of course, primarily and essentially a British Order, but provision will be made for taking into its ranks distinguished foreign personages as honorary members. The badge of the Order, to be worn by its members, will consist of a cross of red and blue enamel of eight points, having the words "For Merit" (the motto of the Order) in gold letters within a laurel wreath on a blue enamel centre. The reverse of the badge will show the King's Royal and Imperial cipher in gold (two silver swords with gold hilts, placed saltirewise between the angles of the cross, being added in the case of members chosen for military or naval distinction) also within a laurel wreath, on a blue enamel centre; and the whole will be surmounted by the Imperial Crown enamelled in colour, and suspended by a parti-coloured ribbon of Garter blue and crimson, two inches broad. The Sovereign's insignia, except, of course, for the modifications necessary to distinguish the Royal dignity of the wearer, will be similar to the insignia worn by the ordinary members of the Order. The ceremony of the investiture will be from time to time conducted by the Sovereign as in the case of any other Order, the members designate being introduced by the officer of the Order in attendance. Members of the Order will be entitled to attach a facsimile of its badge and ribbon to their arms. The Seal of the Order will show a facsimile of the badge, impaled with the Royal Arms, on a white ground, with the legend "The Seal of the Order of Merit." June 26, as the day originally fixed for the Coronation ceremony, will be observed as the anniversary of the Order.

The Order only comprises one class of ordinary members, and of the twelve eminent men chosen as the first to be admitted, four are men whose names are familiar throughout the world of science.

Among the new Privy Councillors are Lord Kelvin and Lord Lister.

The new Baronets include Sir Andrew Noble, K.C.B., Sir Francis Laking and Sir Frederick Treves.

The honour of Knighthood has been conferred upon Dr. J. W. Collins, F.R.C.S., Mr. A. Cooper, F.R.C.S., Mr. H. Croom, president of the Royal College of Surgeons (Edinburgh); Dr. T. Fraser, F.R.S., president of the Royal College of Physicians of Edinburgh; Mr. Victor Horsley, F.R.S., Mr. H. G. Howse, president of the Royal College of Surgeons; Principal Oliver Lodge, F.R.S., Prof. W. Macewen, F.R.S., Principal Rücker, F.R.S., and Mr. J. Thornycroft, F.R.S.

In the Order of the Bath (Civil Division) Sir William Church, Bart., president of the Royal College of Physicians, and Prof. W. Ramsay, F.R.S., have been appointed Knight Commanders. Major Ronald Ross, F.R.S., and Prof. A. M. Worthington, F.R.S., have been appointed Companions of the same Order.

In the Military Division of the Order of the Bath, Admiral Sir Erasmus Ommanney, F.R.S., has been appointed Knight Commander.

The Kaisar-I-Hind medal for public service in India has been granted to Mr. Edgar Thurston, superintendent, Government Central Museum, Madras.

Finally, the new Order of Merit includes the names of four distinguished men of science, namely, Lord Rayleigh, Lord Kelvin, Lord Lister and Sir William Huggins.

NOTES.

It is announced that Signor Schiaparelli has been elected an associate of the Paris Academy of Sciences in succession to the late Baron Nordenskiöld.

The Albert medal of the Society of Arts for the present year has, with the approval of H.R.H. the Prince of Wales, president of the Society, been awarded to Prof. Alexander Graham Bell, "for his invention of the telephone."

The Panama Canal Bill, which was adopted by the United States Senate a few days ago (p. 205), has been accepted by the House of Representatives and signed by President Roosevelt, so that it has now become law.

The summer excursion of the Geologists' Association this year will be to the Ipswich and Norwich districts, the directors being Mr. W. Whitaker, F.R.S., and Mr. F. W. Harmer. The party will leave London on Saturday, July 26, for Ipswich, which will be the headquarters until July 31. Norwich will then be the centre until August 5, when the party will return to London.

The council of the Society of Arts offers the Fothergill prize of 50*l.* and a silver medal for a paper on "Existing Laws, Bylaws and Regulations relating to Protection from Fire, with Criticisms and Suggestions." The paper should consist of about eight to ten thousand words, and be written with a view to its being read and discussed at an ordinary meeting of the Society. Papers submitted for the prize must be sent to the secretary on or before October 1. Each paper must be typewritten, and bear a motto, the name of the writer being enclosed in a sealed envelope with a similar motto. The judges will be appointed by the council.

Reports of recent volcanic disturbances and related effects continue to be published. A despatch from Honolulu says that a violent eruption from the Kilauea volcano took place on June 3. It is further stated that when the Mont Pelée eruption was at its height, and during the six hours St. Pierre was overwhelmed, there were marked magnetic disturbances in the observatory on Oahu Island. A telegram from Fort de France to the French Minister of the Colonies, dated June 26, says that the scientific expedition which was sent to Martinique considers that the destruction of St. Pierre was caused by a rush of gas at a very high temperature, travelling from north to south. The destruction of Le Prêcheur and Ste. Philomène is attributed to torrents of mud, which overwhelmed them. No appreciable sinking of the sea bottom near the coast has been found.

Evidence of the assistance given to agriculture by the Technical Instruction Committee of the Essex County Council is afforded by the report just published on the various branches of work carried on. Farmers within the administrative County of Essex can obtain from the County Laboratories, for a nominal fee, reports upon chemical, botanical and entomological specimens and materials. Thus, for the fee of one shilling for each subject, reports can be obtained upon the germinating power and purity of seed; the species of a weed or other plant, with a report on its nature and habits and any means of checking or destroying its growth; any disease affecting farm or garden crops; any insect or other pest affecting farm or garden crops, or stock, with advice as to its prevention or destruction. Work of this kind forms a very valuable part of the functions of Technical Instruction Committees in agricultural districts. The biological work carried on under the auspices of the committee has been of a very helpful character. To enable teachers in rural schools to obtain a knowledge of natural history sufficient to inspire interest in it in their pupils, class and field meetings were held during the year and proved very successful. The subject selected for systematic treatment was plant-life, considered in its broadest sense, so as to give the teacher-students a fairly interesting introduction to the wider subject of nature-study.

At the meeting of the French Society for the Encouragement of National Industry held on June 13, the Minister of Marine announced that, following the recommendation made at the congress held at Zurich in October, 1900, as to the adoption of an international system of screw gauges, he had, with the concurrence of his technical advisers, decided to render the new system a service regulation so far as it concerned the heads and worms of screws. He had accordingly given instructions that for all sizes used in the French navy the length should be made equal to 1·4 diameters plus 4 millimetres (L = 1·4d. + 4mm.); so that from any one part every bolt could be distinguished at first sight from the bolts of other dimensions, either by the head or by the body of the screw; and that, leaving out exceptional cases, the sizes should be determined by the above simple formula.

The twelfth international congress of the International Tramways Union and the second International Tramways and Light Railways Exhibition were opened at the Agricultural Hall, Islington, on Monday, by Mr. Gerald Balfour, President of the Board of Trade. Mr. Gerald Balfour, in proposing "The Union Internationale Permanante de Tramways," at the subsequent luncheon, remarked that in the industry represented by their own international union, he was afraid that this country had probably more to learn from distinguished friends who had come from the other side of the Channel than they had to learn from us. He hoped that this inferiority, of which he was painfully conscious, was not going to last for ever. In this country we had been taking a nap, but he thought he saw some signs of an awakening. It was with the introduction of the overhead trolley system that the supremacy of electric traction and light railways was established. He believed that this system was not so quickly appreciated in the United Kingdom as it was by our neighbours. The consequence was that we had undoubtedly got a little behind.

The annual general meeting of the Marine Biological Association of the United Kingdom was held in the rooms of the Royal Society on June 25. The officers and council elected for the year 1902–3 were as follows:—President, Prof. E. Ray Lankester, F.R.S.; hon. treasurer, Mr. J. A. Travers; hon. secretary, Dr. E. J. Allen; council, Mr. G. P. Bidder, Mr. G. C. Bourne, Mr. Francis Darwin, Prof. J. B. Farmer, Dr. G. H. Fowler, Dr. S. F. Harmer, Prof. W. A. Herdman, Prof. G. B. Howes, Mr. J. J. Lister, Prof. E. A. Minchin, Prof. C. Stewart, Prof. D'Arcy W. Thompson and Dr. R. N. Wolfenden. The following governors are also members of council:—Mr. J. P. Thomasson (the prime warden of the Fishmongers' Company), Mr. E. L. Beckwith (Fishmongers' Company), Sir J. Burdon Sanderson, Bart. (University of Oxford), Mr. A. E. Shipley (University of Cambridge), Prof. W. F. R. Weldon (British Association for the Advancement of Science). Special reference was made in the report of the council to the loss sustained by the Association through the death of Mr. Robert Bayly, one of the governors of the Association, whose generous support and valued assistance contributed very largely to the successful establishment of the laboratory at Plymouth.

Dean Hole presided at the conference on roses organised by the Royal Horticultural Society in connection with the Coronation Show at Holland House on Tuesday, June 24. He had much to say in praise of the blossoms with which his name is associated, and having commented on the value of the papers to be read, called upon Mr. J. G. Baker, F.R.S., to give an

account of *Rosa stellata* and *R. minutifolia*, recently discovered in New Mexico and California respectively. These roses are characteristic, the first having its leaves, or rather the three terminal leaflets, arranged like those of a Potentilla and unlike any other allied species. *R. minutifolia*, as its name implies, has very small leaves which are deeply toothed. These forms are alike in having red flowers, and in habit they resemble the Scotch rose, *Rosa spinosissima*. Only the second species has as yet been grown in this country, and that with little success. The question of the origin of the hybrid tea rose was touched upon by the Rev. J. H. Pemberton in his general paper on this form. Mr. Alexander Dickson stated that as a result of almost a life's work in the hybridisation of roses he had not been able to reduce a single theory to a certainty, and not one feature as regards colour, shape or fragrance could the experimenter ensure in an artificial hybrid. The need for a strain of roses that will stand the English climate was emphasised by Mr. Edward Mawley. Many points of cultural interest were raised, and many papers will appear in the report which time did not permit of being read, such as those on "The Production of New Hybrid Roses," by M. Viviand-Morel, "Wild Asiatic Roses," by M. Maurice de Vilmorin, and "Recently Discovered Chinese Roses," by Mr. George Nicholson.

A PECULIAR appearance at and after sunset was noticed by a number of observers several evenings last week. Dr. C. B. Plowright, of King's Lynn, and some friends with him, observed after sunset a number of rose-red beams of light radiating upward in the western sky, with the sun as the centre. These beams were not of long duration, and changed in position and brilliancy in the course of a few minutes. Sometimes they extended 30° or 40° upwards towards the zenith. On Wednesday, June 25, the beams were brightest about 9.10 p.m. On Friday, 27th, the phenomenon lasted from about 8.50 to 9.10 p.m. After the beams died away, the upper part of the western sky was tinged by a delicate pink haze. Mr. A. R. Jenkin sends a similar account of the beams as seen by him at Trewirgie, Redruth, on June 27, at 8.45 p.m. He noticed at first "a pink glow low down in the south-east, exactly opposite the sun; this soon sent out streamers. Meanwhile, a pink patch of considerable extent had appeared about midway between the horizon and the zenith in the north-west above the sun, and this also quickly resolved itself into rays converging towards the sun corresponding to those in the east, so that at one time they could almost be traced right through the zenith, and one of the rays lower down to the north could be plainly seen right across from west to east. As the western glow increased so the eastern diminished, until at 9 p.m. there was nothing to be seen in the east, but in the west the rays were most striking. Appearing to rise out of a clear belt of lemon-yellow colour along the horizon, they extended high up into the sky. As the sun got further north below the horizon the rays rotated on their axis (the sun) in the opposite direction. They could be distinctly seen up to 9.20 p.m., when they had almost sunk into the belt on the horizon, which by this time was of a similar pink colour."

IT is officially declared that the statement recently made to the effect that the Meteorological Department in India has indicated the probability of a deficiency of rain, more especially in Gujerat, is incorrect. The Government of India have, however, decided not to make public the forecasts which the department submit to them from time to time, on account of the imperfect data on which such forecasts are necessarily based. The weekly reports which are sent home by the Government of India, and published in this country, give the most trustworthy indications that can be obtained, both of the actual facts and of the prospects for the future. The last of these reports, for the week ended June 22, stated that the monsoon had given heavy rain in the west coast districts, light rain in the Deccan and Sindh, and showers in Gujerat. Good rain has also fallen in Burma, Assam and Lower Bengal, and agricultural prospects up to the present are on the whole satisfactory.

THE discussion of the origin of eskers has led to a large amount of literature. Many geologists now believe that these winding ridges of glacial gravel are the product chiefly of the subglacial drainage of an ice-sheet. Mr. W. O. Crosby (*Proc.* Boston Soc. Nat. Hist., vol. xxx. May, 1902) seeks to show that under normal conditions the deposits of gravel and sand formed in a superglacial channel may be let down upon *terra firma* without obliteration and without loss of the distinctive features of an esker.

DR. S. HEPITES has recently issued the fifteenth volume (for 1899) of the *Analele* of the Meteorological Institute of Roumania. One of the most valuable memoirs contained in it deals with the rainfall of the kingdom, and is illustrated by a map drawn to the scale 1 : 1,000,000 and based on observations made during the fifteen years 1884-1898. Dr. Hepites also describes briefly six slight earthquakes felt during 1899.

EARLY last month the *Standard* and other newspapers contained reports of tremors and rumbling sounds observed on the night of June 3 chiefly in the west of Essex. The times given are not very exact, but were roughly about 11.15 and 11.45 p.m. The resemblance to earthquakes must have been somewhat close, several persons accustomed to earthquakes in other countries being convinced that the disturbances were of seismic origin. The long duration of the vibrations, however, and their apparent transmission through the air, point to an artificial origin, and there can be no doubt that they were caused by the firing of heavy guns that took place at the mouth of the Medway at about the times mentioned. The tremors were noticed and were attributed to earthquakes at places as far as North Mimms and Elstree in Hertfordshire, which are 46 miles from the mouth of the Medway, and at Little Shelford, near Cambridge, distant 55 miles.

THE third volume of the *Annales* of the National Observatory of Athens has been published recently. Besides the usual meteorological tables, it contains two memoirs by the director, Dr. D. Eginitis, one on the observation of shooting-stars at Athens during the years 1897–1899, and the other on the earthquakes felt in Greece during the year 1899. From the latter we learn that 567 earthquakes were recorded, the mean annual number for the six preceding years being 531. Of this large number, 421 were felt in Zante, though some were not entirely confined to that island. The most important earthquake was one that occurred on January 22 in the province of Triphylie on the west coast of the Peloponnesus. This was strong enough to throw down houses over a district 18½ miles long and 10 miles wide, though the total area disturbed was less than 15,000 square miles. It was recorded at Shide, in the Isle of Wight, the mean velocity to that station being 2·1 km. per second.

PHYSIOLOGISTS have during late years regarded hæmoglobin and its derivatives in the animal organism as occupying a somewhat analogous position to that of chlorophyll and its derivatives in the vegetable kingdom, a view which may be said to be the outcome of recent chemical and spectroscopical research. It is well known, for example, that these complex organic pigments produce characteristic absorption bands in the ultra-violet part of the spectrum. Just lately, however, it has been shown by MM. L. Bier and L. Marchlewski (*Bulletin International de l'Académie des Sciences de Cracovie*, April, 1902) that this fact is not apparent in the spectra of all the derivatives of the colouring matter of the blood (hæmoglobin); for these observers

have demonstrated by photographs of the spectra of bilirubin, biliverdin, urobilin and proteinchrom that the characteristic bands in the violet part are absent. But from this observation we must not necessarily infer that these organic pigments are not derivatives of hæmoglobin, for, as these investigators point out, the characteristic absorption bands in the violet area of the spectrum produced by the complex molecule of hæmoglobin may not depend on the constitution of the nucleus forming the basis of this complicated mother substance, but may arise from certain atomic groups which may not appear in some of its derivatives.

A CORRESPONDENT directs attention to the absence of any reference to Dr. Gaskell's work in the note in our issue of June 19 (p. 184) on Prof. Patten's account of the affinities of Tremataspis. The same absence characterises Prof. Patten's paper, to which our remarks were restricted.

IN the geological series of publications issued by the Field Columbian Museum, Mr. E. S. Riggs describes the Triassic and Jurassic of the Rio Grande, Colorado, which have yielded so many remarkable dinosaurian remains. The paper is illustrated with some excellent photographic reproductions of the striking scenery of the district.

IN describing a species of "sand-fly" allied to *Ceratopogon albopunctatus*, Mr. W. R. College, in vol. xvii. part i. of the *Proceedings* of the Royal Society of Queensland, states that it is probably only the females of these irritating insects which attack human beings. Out of fifty specimens caught on the author's own hands, only one was a male. The sexes are readily distinguishable by the antennæ, which are plumose in the female and filiform in the male.

WE have received from the authors, Messrs. Eckel and Paulmier, a copy of a synopsis of the snakes of the north-eastern United States published in the *Bulletin* of the New York State Museum and forming the first instalment of a complete catalogue of the reptiles and amphibians of New York. In the present part the distinctions between venomous and harmless serpents are indicated in a clear manner, while the various species are well described and in many cases illustrated by figures of the head.

We have received from the authors copies of two papers relating to the iguanodons of Bernissart, in Belgium, and the nature of the country at the time of the entombment of their remains. The one, by Mr. L. F. de Pauw, who restored the skeletons, appears in vol. iv. of the *Memoires* of the Hainaut Scientific Society, while the other, by Prof. van den Broeck, is issued in the *Bulletin* of the Belgian Geological Society for the present year. Both writers support the view of Messrs. Cornet and Schmitz that the Bernissart iguanodons inhabited the margins of a lake, and not, as has been supposed, a narrow gorge cut in Carboniferous rocks and filled up by deposits of Wealden age. The features in the section which led to the promulgation of the latter view may be explained by earth-movements of post-Wealden age. Mr. Pauw has made an interesting restoration of a group of iguanodons round the old Bernissart lake, a photographic reproduction from which accompanies the memoir. The author believes that these reptiles often walked on all fours, especially when leaving the lake.

AMERICAN naturalists are devoting more and more attention to the mammals and other vertebrates of the Old World, and by means of vigorous collecting are adding largely to the list of species and races. In the *Proceedings* of the U.S. Museum, for instance, Mr. G. S. Miller describes a large collection of mammals from the Andaman and Nicobar Islands, in the course of which he names a number of mice, as well as other forms. No less than thirty-five species of mammals are definitely recognised from these islands. Another paper by the same author, dealing with oriental mammals, based on specimens collected by Dr. W. L. Abbott on the islands of the Malay and China seas, appears in the *Proceedings* of the Philadelphia Academy for March, and likewise contains descriptions of a number of forms regarded as new. In a third contribution, published in the journal last mentioned, Mr. A. E. Brown describes a collection of reptiles and amphibians from Borneo and the Liu-kiu Islands, in the course of which a few new names are proposed. In the case of mammals, forms inhabiting different islands, no matter how closely related, are regarded as distinct.

THE *Lancet* of June 21 publishes the report of a lecture delivered by Dr. Rose Bradford before the University College Medical Society on the relation of biology to medicine. After remarking that the subject may be regarded from three points of view—from its educational value, from its relation to practice, and the influence which it has exerted, and probably will exert, on the progress of medical research—the lecturer calls attention to the value of biological study, and more especially to the work of the field-naturalist, as a means of promoting accurate observation. Biological studies, both anatomical and physiological, have a further great advantage to the medical student in giving him a broader conception of the complexity of living matter than if he confines his studies to the human subject. In regard to the relation of biological study to medical practice and research, Dr. Bradford emphatically urges its importance, pointing out the number of diseases now definitely known to be due to animal or vegetable organisms, such as malaria and other blood-affections, and the morbid processes originated by the presence of funguses. It is further suggested that the true nature of cancer may be discovered by biological rather than by purely pathological researches. The lecture concludes by emphasising the importance of a careful study of variation and heredity to the medical practitioner who hopes to advance his profession.

THE Report of the Field Columbian Museum of Chicago for 1900–1901 indicates a continued and rapid progress of this institution. "Inappropriate and undesirable material," writes the director," is constantly disappearing, to be supplanted by that which is nearer the standard, and the Museum is doing *museum* work; while the laboratory and the study are not neglected, yet the fact that the Museum is dedicated to the enlightenment, instruction and in a measure to the entertainment of the public is not ignored, and those things calculated to advance this policy are those that most engage the attention of the officers of the institution. As a natural consequence, the general appearance of the Museum is never the same, constant additions, changes and renewals, &c., making the exhibition halls always fresh and inviting." The Field Museum was one of the first to adopt the system of mounting the larger mammals on artificial groundwork in imitation of their natural surroundings, and the Report before us contains a photograph of a big-horn sheep and another of a "sounder" of wart-hogs taken from groups in the Museum, which serve to show the careful and realistic manner in which the plan is carried out. An exhibit of much interest is a model of a limestone cave, with natural stalactites and stalagmite, and specimens of the animals which inhabit such situations. This model is lit up by electricity. The idea is so excellent that it might be adopted by other museums.

THE Hull coins and tokens in the Hull Museum have been described by Mr. William Sykes, an authority on the subject, and issued as one of the illustrated penny guides to the

collections of the Museum. We have previously drawn attention to this excellent series of museum publications, which is due to the energy of the curator, Mr. T. Sheppard.

THE sixth annual report of the New York Zoological Society gives a very favourable account of the progress of the "zoological park" now established on the northern confines of New York, so far as the plans of the Society have yet been carried out. The objects in contemplation by the founders of the association were the creation of a zoological garden with a special view to the preservation of the larger native animals of North America (now, alas! fast becoming extinct) and the

FIG. 1.—Primates' House.

general promotion of the science of zoology. Although the Society is of a private nature, its relations to the city authorities are of the closest kind, and are pronounced in the report on the whole to be in an extremely satisfactory condition. The various buildings in the park are making good progress. One of the chief of them, the "Primates' house," was completed and opened in December last with a series of 114 living specimens of the order Quadrumana, amongst which were two large examples of the rare Gelada baboon of Abyssinia, besides orangs, chimpanzees and gibbons. Of the collections of bears and the herds of prongbucks and other animals, good reports are also given, but as the new "park" contains an area of some 260 acres, it will take some time to fill it. We are glad to see

FIG. 2.—Prong-horned Antelope Herd in 1902.

that the scientific element is well represented on the council of of the Society, as is testified by the names of Dr. Allen and Mr. Chapman, of the American Museum of Natural History, and of Mr. H. F. Osborn, of Columbia University. Besides these authorities, the director, Mr. W. T. Hornaday, is well known in zoological circles. The report is illustrated by a front view of the new Primates' house (Fig. 1), a sketch of the herd of prongbucks (Fig. 2) and other good plates. The present number of members of the Zoological Society of New York is stated to be 1182, which in such a populous and wealthy city might well, we think, be considerably increased if such a valuable institution were supported as it ought to be.

THE harpoon is the most complicated of the devices invented by uncivilised peoples. The harpoon is the climax of piercing inventions, and may be held in the hand or hurled from it with or without the aid of devices for propulsion. It has no limits in its application, being equally efficient on the land, in the air, in the water or through the ice, at long range or short range, with short shaft or long shaft, some examples being known in which the shaft is 100 feet in length. The simplest forms have three rude parts; the most highly developed have a score or more. With characteristic detailed description and wealth of illustration, Dr. Otis T. Mason has published a monograph on "Aboriginal American Harpoons: a Study of Ethnic Distribution and Invention," in the Report of the U.S. National Museum for 1900 (1902, p. 189). As the old whaleship has been replaced by the ship driven by steam, so the Eskimo at present kills the seal, the walrus, the whale and the Arctic land mammals with a rifle and explosive bullets instead of the ancient harpoon. Should the Eskimo use his great weapon at all it will be to retrieve his game on the edge of the ice after it is shot, and not as a killing device.

AN industry that promises to make progress in Russia consists in the manufacture of oil cakes from the seeds of the sun-flower, and (says the *Engineer*, June 20) good results have already been obtained. The seed with a proper crushing and treatment yields, roughly, 23 per cent. oil, 40 per cent. oil cake and 37 per cent. stalk; the stalk is also used for driving the machinery of the mill, and the ash by being further treated produces 25 to 30 per cent. of potash.

"THE Niagara Falls Power Plant as a Factor in Engineering Development" forms the subject of an instructive and impressive article in the editorial columns of the *Engineer* (Cleveland, June 2). The power of the Falls is practically unlimited, for the amount of falling water has been estimated by Prof. Unwin at 300,000 cubic feet per second, and this amount at a head of 165 feet would generate 10,000,000 horse-power. The plant as put down eleven years ago consisted of two-phase alternating current dynamos of 5000 horse-power (250 revolutions per minute), with a voltage of 2200 and a "frequency" of 25 cycles per second; these were coupled to vertical turbines placed in the wheel pit by shafting 136 feet long. The turbines were of double design, whereby at normal load the lifting action of the escaping water would balance the weight of the revolving parts of the machine. This plant, after eleven years' running, is about to be enlarged and a considerable increase of power derived from the falling waters, and thus we find record again broken at Niagara, where three generators (each of 10,000 horse-power) will be placed in the power house on the Canadian side and will form the nucleus of a plant with a 100,000 horse-power capacity. These generators will be double the size of the old ones and three phase instead of two phase, with a voltage of 12,000 as against the 2200 used before, and the "frequency" and speed will be the same, namely, 25 cycles per second of the former and 250 revolutions per minute of the latter. The transmission voltage in all probability will be fixed at 60,000, which, if adopted, will be 10,000 volts higher than that used in California by the Standard Electric Company on their famous long-distance line.

BOTANISTS who are desirous of filling gaps in their herbaria of cryptogamic plants will be interested to know that Mr. J. Brunnthalers of Johann Straussgasse, Vienna, has published a list of these plants which are for exchange or for sale. The series of Pteridophyta is exceedingly meagre, but the remaining groups are fairly well represented.

A BIBLIOGRAPHY of the analytical chemistry of manganese from 1785 to 1900 has just been published by Messrs. H. P.

Talbot and J. W. Brown, and forms part of vol. xli. of Smithsonian Miscellaneous Collections. The same volume contains a compilation of the statistics of the chemical societies of the world for the year 1900, by Dr. H. C. Bolton.

ACCORDING to a new patent of the Chemische Fabrik Griesheim-Elektron, lead dioxide is now produced electrolytically from a solution of an alkali chloride in which litharge is suspended. The dioxide is formed at the anode by the action of nascent chlorine and sodium hypochlorite on the sodium plumbite produced from the litharge and the sodium hydroxide set free at the kathode. No loss of chlorine takes place at the anode during this electrolytic process.

VOL. xxxvii. of the *Proceedings* of the American Academy of Arts and Sciences contains the results of an investigation of the decomposition of mercurous chloride by dissolved chlorides, by Messrs. T. W. Richards and E. H. Archibald. It is shown that this decomposition is quite considerable if the chloride solutions are fairly concentrated, a point of considerable importance in the analytical determination of mercury as mercurous chloride. The action is not of a catalytic nature, but a definite condition of equilibrium is set up, the dissolved mercury existing probably in the form of a complex ion represented by the formula $HgCl''_4$ in the solution.

WHILE admitting that the evidences of embryology, vestigial traces, and geographical distribution have rendered it indisputable that species have arisen in our world, not through creation in each fresh case, but through descent from other kindred species with variation, Mr. James B. Johnston maintains, in an article "What About Natural Selection?" in the *Contemporary Review* for July, that the proved influence of natural selection is being written down as less and less every day. The article is concerned only with the evidence of palæontology.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. J. M. Hemingway; an African Tantalus (*Pseudotantalus ibis*) from West Africa, presented by Mr. C. T. Reaney; two Black Salamanders (*Salamandra atra*), an Alpine Newt (*Molge alpestris*) from the Alps, presented by the Rev. J. W. Horsley; a Common Viper (*Vipera berus*) British, presented by Mr. E. Ball; a Chacma Baboon (*Cynocephalus porcarius*), a Natal Sternothere (*Sternothoerus sinuatus*), from South Africa, a Ludio Monkey (*Cercopithecus ludio*) from West Africa, two Grey Lemurs (*Hapalemur griseus*) from Madagascar, two Azara's Opossums (*Didelphys azarae*) from La Plata, a Botta's Snake (*Charina bottae*) from North America, deposited.

OUR ASTRONOMICAL COLUMN.

CHANGES ON THE MOON.—The June number of the *Century Magazine* contains a popular account of the observations of the moon made by Prof. W. H. Pickering at Flagstaff, Arizona, and Jamaica, illustrated with pictures from drawings and photographs. Previous workers have already shown that some markings on the lunar surface were in all probability of a variable nature, but the new observations demonstrate beyond doubt that the surface of the moon is subject to distinct changes, and Prof Pickering gives some very decisive instances where radical alterations have actually been observed. Attention also is drawn to the existence of seas, canals and lakes on our satellite's surface, terms which have very generally been adopted with reference to the planet Mars, but which are employed here with the full understanding that they do not imply in any way the existence of water in the liquid form. These canals are described as being smaller than those on Mars, but broader in proportion to their length; in colour they are grey and yellowish-white. Many of the changes on the lunar surface are caused by the growth, as Prof. Pickering states, of the lunar vegetation itself, and he quotes a particular region situated just to the right of the central peaks of Eratosthenes where he observed the most marked change; reference is further made in some detail to the changes observed in some of the canals and lakes. The importance of these observations to selenography and the great interest attaching to them should undoubtedly stir up a new desire in many workers to follow and continue these researches, which require no very great instrumental equipment.

REMARKABLE NAKED EYE NEBULOSITY.—MR. W. H. Robinson, writing from the Radcliffe Observatory, Oxford, sends us a description of a curious object observed by him on May 28. Whilst observing with the Radcliffe transit circle at 11h. 19m. G.M.T., his attention was directed to a nebulous object about eight degrees from the zenith. "It was small, but bright and well defined, elliptic in form (major axis 2°, minor axis 1°·5), and situated about half-way between η Ursæ Majoris and α Lyræ, but a few degrees south. The object very much resembled the Præsepe when that cluster is visible in a somewhat hazy sky, an atmospheric condition which prevailed at this time. At first I supposed the object to be a comet, but was soon disillusioned on this point, for in a few minutes its evanescent character was revealed, and, gradually fading, by 11.30 G.M.T. it had entirely disappeared."

The position of the nebulosity was found by means of a star atlas to be

R.A. 16h. 15m.
Decl. + 44°.

The sky was watched until midnight for any return of the phenomenon, but nothing was seen except at about 11h. 42m., when a faint patch of light appeared for a few seconds only, about two degrees east of the above position. The luminosity was apparently not of an auroral nature, and Mr. Robinson suggests that it may have been the trail of a meteor, several instances of meteor clouds of this character having been recorded.

Other observations of the object observed on May 28, if forthcoming, would probably enable a determination to be made of its distance and nature.

A THEORY OF VOLCANOES.—In a forcible exposition of a theory which supposes high-tension terrestrial electricity to be the immediate cause of volcanic eruptions, M. A. Taquin, in the *Revue Scientifique* for June 14, brings together some remarkable observations of the connections between volcanic, solar, magnetic, and terrestrial electrical phenomena. The author provides for the disruptive forces and the heat which attend volcanic actions, by the discharge of this high-tension electricity, and then connects this electricity with the previously observed relations between solar, and terrestrial electrical and magnetic phenomena.

M. Taquin accounts for the remarkably sudden deaths of the inhabitants of St. Pierre by supposing that they were electrocuted, and proceeds to urge, in the following words, the establishment of observatories in volcanic districts:—"I am convinced that the study of the manifestations of terrestrial electricity in such districts will give us the means of foreseeing these volcanic eruptions."

THE FRENCH GEODETIC MISSION TO THE EQUATOR.—Commandant Bourgeois gives an interesting and detailed account of the first year's work of the French geodetic expedition in the *Bulletin de la Société Astronomique* (June, 1902). M. Bourgeois first explains that the *raison d'être* of the mission is "to determine certain elements by which to calculate the dimensions of the earth," and he then proceeds to answer the following self-imposed questions:—(1) What are these elements? (2) How are they to be determined? (3) Why is it necessary to make the observations in a place which is so distant and so difficult to reach? In answering these questions the author describes the inauguration, the organisation, and the journey of the mission to Riobamba, Ecuador, S.A., and also explains why Riobamba was fixed upon as the centre of operations. The whole report, which was communicated to the Société Astronomique, gives an instructive account of the work already achieved, and is illustrated by photographs which give the reader a clear idea of the methods pursued by the mission.

OBSERVATIONS OF NOVA PERSEI.—In No. 3796 of the *Astronomische Nachrichten*, Prof. E. E. Barnard gives a brief *résumé* of the various observations of the Nova which were made at Lick subsequent to July, 1901.

The spectrum of the Nova suggested that it might display the same peculiarity of focus hat we find in regard to planetary nebulæ, but a series of observations made between August, 1901, and January, 1902, failed to give any indications of this phenomenon.

The determined position of the Nova with regard to fourteen stars in its immediate vicinity—of which Prof. Barnard gives a chart—agrees fairly well with that already published by Prof. Aitken (Lick Observatory *Bulletin*, No. 8), and a comparison of the two sets of observations confirms no real motion of the Nova.

The observations of brightness, which extend from July 30, 1901, to April 15, 1902, show a gradual decrease in the magnitude of the Nova, with occasional brightenings in which, however, there appears to be no definite periodicity. After special measurements, Prof. Barnard disagrees with the Potsdam magnitude of the reference star B.D. 43° 270 and uses his own estimated value, which is about 0·2m. fainter than that of Potsdam, *i.e.* it is 7·56m.

Careful observations with the great telescope have failed to reveal, visually, the nebulosity surrounding the Nova, the light of which is probably mainly photographic, nor has Prof. Barnard been able to discover the 12·0m. star recorded by Prof. Ceraski as being 0·31s. following and 7″ south of the present position of the Nova (*Astronomische Nachrichten*, No. 3755).

NEW VARIABLE STARS.—The two new variables, as given below, are recorded in No. 3796 of the *Astronomische Nachrichten*.

11, 1902, *Lyrae*.—Mr. Stanley Williams reports the variability of the star, the position of which, as measured on various negatives, is 19h. 7m. 37s.·4 +41° 3′·7 (1855); its magnitude ranges from 11·10 to 12·20. Examination of the various records shows that the brightness of this star was approximately the same, in September, in 1899, 1900 and 1901, so that its period is probably exactly one year, or possibly one half-year.

12, 1902, *Pegasi*.—Herr K. Graff reports the variability of the star, the position of which is 22h. 7m. 30s.·15 +14° 4′ 10″·0 (1902), its range of variability being from 8·7m. to 9·4m.

DELAY OF THE MINIMUM OF U CEPHEI.—In No. 3796 of the *Astronomische Nachrichten*, Mr. J. Plassman records a delay of about 2h. 27m. in the minimum of U Cephei, on April 27, after the time of minimum recorded at Münster.

EARTHQUAKE NOTES.

THE seventh and eighth numbers of the new series of publications issued by the Earthquake Commission of the Kaiserlichen Akademie der Wissenschaften in Wien respectively refer to earthquakes which have been noted in certain parts of the Austrian Alps and in the Carpathians. The first of these, by Dr. R. Hoernes, is a register of 208 shocks observed in Styria between the years 1000 and 1870. Many of these disturbances are described in detail, and to each description there is appended a criticism of the various sources from which the author has derived his information. To complete this work, earthquakes which shook Styria, but originated beyond its borders, have to be considered, and, lastly, the districts shaken and the lines along which shocks have been distributed have yet to be determined. In short, what E. Suess has done for lower Austria and H. Hoefer for Carinthia is to be done for Styria. The second publication, by Prof. W. Láska, is an historical account of the earthquakes of Poland. It refers to a period practically identical with that considered by Dr. Hoernes. The author commences by saying that "earthquakes in Poland are rare," but as reference is made to earthquakes of distant countries which were synchronous with observations made in Poland, the description of Galician shocks extends over thirty-six pages. As an example of these references we read that the first earthquake in 1834 occurred on January 23 at 8h. 45m. and was observed in Tarnopol. On the same day there was an earthquake in England, the epicentrum of which was five miles north of Chichester, and it is worthy of note that there was a similar coincidence in 1666. The probability, however, is that if we had before us a register of all the earthquakes of the world, a coincidence might be found for each of the Carpathian records. In the general remarks attached to these registers we find several interesting notes on the emotional effects produced by those who have predicted the occurrence of earthquakes on specified dates. An accidental realisation of a widely published prediction took place on February 27, 1786, with the result that processions were organised and prayers were offered that earthquakes should not only shake Poland, but that a few should be arranged for Prussia.

In November, 1900, Prof. E. Odone gave an account in the *Bollettino della Società Sismologica Italiana* (vol. vi.) of forms of apparatus he proposed to introduce into seismometry which did not have the character of pendulums. The object of the first piece of apparatus was to measure the relative motion of two points of ground separated by a short distance. A seismographic arrangement identical with that proposed by Prof. Odone was used in Japan in the years 1884 and 1885. It showed that for fourteen earthquakes the relative motion of the heads of two stakes 3 feet from each other varied between 1 mm. and ·08 mm. (*Trans. Seis. Soc.*, vol. xii. pp. 63–66). The second piece of apparatus has the character of a manometer, and in its improved form as now constructed is described in the *Rivista di Fisica* (Pavia), December, 1901. It consists of a chamber about 2 m. in height and holding 200 l. of water, embedded in the foundations of a wall. At the upper and lower ends of this chamber are two passages closed by sheets of iron. On one side these sheets are in contact with the soil in which the foundations are buried and on the other side with the water of the manometer. Should a shock be transmitted through the soil, these metal diaphragms are deflected, with the result that the water from the chamber rises in a small tube 0·85 cm. in diameter, which is attached to the upper end of the manometer. The effect of vibrations due to explosions of powder in mines—in one instance amounting to 10,000 kgr., the apparatus being at a distance of 1 km.—have been studied, and it is seen that the changes of level in the manometric gauge are such as can be easily measured. From this apparatus it is expected to obtain certain direct measurements of earthquake energy, and from a manuscript note attached to the copy of the paper describing the same it is also anticipated that it may record volcanic sounds.

STATISTICAL METHODS IN BIOLOGY.

THE third part of *Biometrika*, published in April, contains several important contributions, the first of which is by Prof. Karl Pearson, who describes "a systematic method of curve-fitting by moments." For practical purposes it is found that if good quadrature formulæ are used this method is as good as the well-known method of least squares, and in some cases is applicable where the older method fails. Examples of the application of the new method are given. A communication on the sources of apparent polymorphism in plants comprises an editorial introduction and four papers by Messrs. G. Udny Yule, W. L. Tower, Dr. Alice Lee and Prof. Karl Pearson, and Mr. Yule respectively. Those who have considered the "multimodal" character of many botanical distributions as furnishing evidence of the existence of subspecies or local races will find reasons for reconsidering their views in these papers. In this part also Prof. Pearson contributes a controversial paper under the title "On the Fundamental Conceptions of Biology," in which he deals with discontinuity, differentiation and variation, and replies to Mr. Bateson's criticism of his memoir on the principle of homotyposis published in the *Philosophical Transactions* (vol. cxcvii. pp. 285–379). Another controversial paper by Prof. Weldon deals with Prof. De Vries's first volume on the theory of the mutation of species ("Die Mutationstheorie," &c., Bd. 1, 1901). The facts adduced by De Vries in favour of this intermittent and apparently anomalous mode of evolution are considered by Prof. Weldon to be inconclusive, and he comes to the conclusion that the evidence is insufficient to warrant the acceptance of this theory in preference to the selection theory of Darwin.

Among other contributions we may call attention to Mr. Blanchard's paper on "grandparental inheritance," in which he emphasises the need for further experimental work on "blending" as distinguished from "alternative" inheritance, and suggests for this purpose insects and some of the smaller mammals. Miss Lewenz publishes the completion of an investigation first started by Miss Whiteley and Prof. Pearson on the variation and correlation of the bones of the hand in woman. The conclusion is suggested "that if efficiency depends on high correlation, it is not to external measurements of the skull that

we must look for tests of intellectual efficiency." Not the least interesting paper at the present time is Dr. W. R. Macdonell's note on the result of previous vaccination on the effect of small-pox when incurred. According to the abstract " he shows that the correlation of foveation and size of scar with severity of attack is only moderate, but that there is very considerable correlation indeed in all the recent epidemics, not only between recovery from, but between the severity of the attack and the existence of the scar." It has not hitherto been found possible to obtain statistical data for deducing the correlation between the presence of the scar and the habit of life of the persons attacked. To the miscellanea Mr. Yule contributes a note on local death rates. It is evident from this synopsis that the standard of the publication is being well maintained and that the new biometric methods are capable of extension over the most diverse fields of biological science.

AVIAN ORGANOGENY.[1]

DR. MITCHELL has already devoted considerable attention to the study of the intestinal tract of birds, and in the present contribution he gives us the results of his latest researches, which have embraced all orders of birds and many of the smaller groups.

Adopting the method of investigation pursued by Cuvier, the intestinal tract is removed from the body by severance at the plyorus and the cloaca, and along the mesentery close to the body-wall. Next, the cut ends of the gut are pinned down and its coils unravelled, until they stand revealed as a corrugated tube suspended by the ventral edge of the mesentery.

In tracts so displayed, Dr. Mitchell recognises three distinct loops, a duodenal, a rectal, and a large loop lying between these two which he calls Meckel's tract. The comparison of the varied forms which these loops take constitutes the subject of Dr. Mitchell's researches.

Evolution is rightly the key-note of this work, and accordingly the author starts with a detailed description of what he regards as the most primitive type of gut, from which all others have been derived. This type—found not, as one might have expected, in one of the Ratitæ, but in the ancient goose-like bird, Palamedea—he calls the archecentric type, whilst modified conditions thereof are distinguished as apocentric. Three kinds of apocentricity are recognised—multiradial, uniradial and pseudocentric. Multiradial apocentricities are those which are purely adaptive or homoplastic, and accordingly are of no value as indications of kinship, since they may, and do, occur repeatedly and independently in different groups. Uniradial apocentricities, on the other hand, Dr. Mitchell defines as complex modifications "of a kind that we cannot well expect to be repeated independently, and. . . . must be the most certain guides to affinity."

Not seldom a uniradial apocentricity will form a new centre around which new diverging modifications are produced, and such centres he proposes to call metacentric.

Pseudocentric apocentricity appears to be extremely common and very difficult to distinguish from the archecentric condition. Generally, however, its secondary nature is revealed by some small and apparently meaningless complexity.

The valuation and nomenclature of these characters form a special section of Dr. Mitchell's paper. It is extremely suggestive, and will be read with interest by many who are not directly interested in avian morphology.

The systematic description, which follows this discussion, occupies the bulk of the paper, the intestinal tract of every order of birds being reviewed, copious illustrations serving to bring out, not only the very striking modifications which have taken place, but also the difficulty of the work undertaken.

Space forbids us dwelling, as we would fain do, on this section and the summary thereof at greater length. Suffice it to say that the very remarkable modifications of these loops, which Dr. Mitchell has brought to light, are extremely interesting and very suggestive. We venture to doubt whether a good case has been made out for the position, near the Ralline forms, which has been assigned to the Tinamous. Markedly apocentric though they may be in the matter of their intestinal coils, yet we see no reason why they should not be allowed to remain among or very near the Ratitæ.

The concluding section, on "Characters and Classification," forms a most admirable summary. "In the systematic descriptive part," the author writes, "my task was to treat the characters of the patterns displayed by different birds as nearly as possible as if the gut were the whole animal, and the various phylogenetic figures and the three plates display what I take to be the relations of the intestinal tracts, and not necessarily the relations of the possessors of these tracts. I have been taking, in fact, the anatomical structure as the unit, and not the individual or the species. . . . Granting that the plates attached to this paper represent with approximate accuracy the phylogeny of the intestinal tract in birds, we have yet to learn the relation of the phylogenetic tree of this structure to the phylogenetic trees of other structures, and the relation of all these to the phylogenetic trees of those impermanent combinations of characters which we call species."

We would fain quote more of this interesting section, but enough has, we trust, been set down here to draw the attention of morphologists generally to a contribution which is at once valuable and suggestive, and likely to remain the standard work of reference on this subject for some years to come.

W. P. P.

[1] "On the Intestinal Tract of Birds: with Remarks on the Valuation and Nomenclature of Zoological Characters." By P. Chalmers Mitchell, M.A., D.Sc. (*Trans.* Linn. Soc., vol. viii. part vii. 1901.)

PHOTOGRAPHY AS APPLIED TO ARCHITECTURAL MEASUREMENT AND SURVEYING.[1]

WHILE the impressions which a photographic picture yields to a casual observer may or may not be correct, the relationship which exists between a photograph and the objects the images of which are depicted is always definite, and a little careful attention in arranging the conditions under which a picture is taken will suffice to make easy the correct interpretation of it.

To understand the geometric nature of a photograph it must be noted and always remembered that for practical purposes a photograph is a surface of two dimensions, which for choice should be a plane surface, and it is only possible to obtain by photography exact copies of similar object surfaces, and these only when the surfaces to be copied are exactly parallel to the picture surface.

Under these conditions written or printed documents or drawings can be, and often are, copied by photography, so as to be practically exact copies of the originals. The copies may be the same size, or larger or smaller, but all proportionate dimensions will be the same, whatever the relative sizes of object and image may be.

To illustrate the first elementary principles of the subject a photographic picture of straight lines and right angles, arranged to form a set of regular squares, was projected on a movable screen. It was shown how, when the screen was parallel to the lantern slide, there was no perceptible bending of the lines and no perceptible enlargement or diminution of any of the angles, from which it might be concluded that there could have been no perceptible distortion in any part of the picture. By moving the screen nearer to, and further from, the lantern, it could be seen that while the forms of the squares remained constant their areas varied with the distance, in obedience to the ordinary laws of rectilinear radiation, from a point, and it was shown how a photographic picture may be legitimately regarded as being made up of a number of points, each one of which is at the picture end of a straight line, which may be taken for practical purposes to have travelled from a corresponding object point through a station point at the apex of a cone of rays radiating towards the picture.

The geometric relationship between distant objects and photographic images of those objects can be most easily appreciated if the lens is supposed to be replaced by a pinhole at the station point, when it is evident that a straight line from any point of the image to the pinhole will, if prolonged, pass through the corresponding object point, and *vice versâ*. Thus any number of true direction lines can be obtained at will.

For making plans, these direction lines can be projected as horizontal rays on a ground plane as in plane table surveying, and positions can be fixed on the plan by the intersection of

[1] Abstract of a paper, by Mr. J. Bridges Lee, read before the Society of Arts on April 16.

such rays from two stations, and checked by rays from photographs taken at a third station when the original intersections are not good or the identification of points doubtful.

When the positions on a ground plan have been fixed and horizontal distances from the different stations have become known, altitudes of points above or below the station can be ascertained by observing the position of the points on the picture and substituting values in a simple formula $h = d \tan \alpha$, where h is the height required, d is distance from the station

FIG. 1.—View from roof of Drummond's Bank overlooking Trafalgar Square.

point for the particular photograph under observation and $\tan \alpha$ is $\sqrt{\frac{y^2}{x^2+f^2}}$, where x and y are abscissæ on the principal horizontal and vertical lines as rectangular coordinate axes and f is focal distance for the picture. The practical working of this method of plotting horizontal intersections for obtaining a ground plan and then computing altitudes was illustrated by reference to a series of survey photographs from the south and

FIG. 2.—View from corner of roof of Union Club overlooking Trafalgar Square.

west sides of Trafalgar Square, looking north-east and east, and a plan of the square and neighbourhood on which horizontal traces of the picture planes were drawn. It was explained how in practice the horizontal distances of points from the principal vertical line of a photograph are first set off on narrow strips of paper, which are then transferred to the picture traces on the plan and direction lines set off from the station points through the selected points on the strips, when in all cases the direction lines would pass through the corresponding points on the ground plan of Trafalgar Square and the visible region round. It was also explained how to compute the height of St. Martin's Church from the pictures.

Two of the pictures used for illustration are here reproduced. It will be seen that these pictures bear some markings on their faces which are not usually found on ordinary photographic pictures.

(1) The horizontal line right across the picture is the horizon line, which marks the trace of the horizon plane of the lens (or station). It contains the principal axis of the lens.

(2) The vertical line is the trace of the principal vertical plane, which also contains the principal axis of the lens and the station point.

(3) The intersection of (1) and (2) is the centre or principal point of the picture perspective.

(4) The scale at the top is part of a compass scale, and serves to show the magnetic orientation of the principal axis of the view, the vertical line serving as index.

(5) The scale immediately below, which stretches as a band across the picture, is a scale of reduced horizontal angles (a tangent scale to a great circle of a sphere of radius equal to the exact working focal length).

The MS. notes in the corners are memoranda originally noted on slips of celluloid by the photographer and put in place in special carriers before each picture was taken. All these markings were printed as latent images at the same time exactly and by the same exposure as the picture.

It was explained how all these markings were accurately obtained by aid of a simple mechanism specially designed by the author, who is responsible for introducing the system of recording automatically on the picture face information necessary for interpreting the picture, and how by aid of this information practical photo-surveying, which used to be often difficult, has become very easy and much more certain and accurate than formerly. The apparatus specially designed by the author and used for obtaining these pictures was shown and explained in some detail.

The lecturer concluded by expressing a hope that in due time a simple standard type of working camera, fitted with a good lens and accurate recording mechanism (which could be easily removed and replaced at will), would find its way into general favour, and that regular libraries of standard readable pictures of interesting objects would come into existence.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following is the text of the speeches delivered by Prof. Love in presenting Dr. W. H. M. Christie, C.B., F.R.S., Astronomer Royal, and Dr. A. W. Rücker, F.R.S., Principal of the University of London, for the Degrees of D.Sc. *honoris causa*, at the Encænia, on June 24.

Inter mathematicos, qui Cantabrigiæ quattuor et triginta abhinc annos graduati sunt, clarum erat nomen Willelmi Henrici Mahoney Christie, nunc inter omnes omnium gentium astronomos clarissimum. Astronomorum profecto ille annus magno proventu floruit cum in eodem Tripode Georgii Darwin nomen contineatur. Ambo hi viri Collegii Sanctæ Trinitatis socii creati sunt, sed in astrorum scientia alter alteram insistebat viam. Ille solis stellarumque soli parentium ultimam vetustatem investigabat: hic noster se negotio utiliori dedit ut solis stellarum siderumque omnium et locos qui nunc sunt et motus accuratissime notaret. In hoc opere tantam peritiam adeptus est ut iam viginti abhinc annos et Astronomus Regius et Societatis Regalis Sodalis crearetur. Hoc gubernante fere omnia in Observatorio Regio maximo vel novata vel in melius mutata: neque enim id solum curavit ut novis instrumentis cederent vetera, sed ut eadem paullo immutata idonea fierent ad sidera observanda observationesque ita factas memoriæ tradendas quemadmodum iubent astronomi recentiores. Ita vir peritissimus et rem felicissime navavit et ærario publico pepercit. Summa eius in rem publicam merita agnovit Regina nostra Victoria quæ eum titulo Comitis de Balneo ornavit: insigni honore prosecutæ sunt Academiæ Parisensis Petropolitana aliæque complures quæ eum inter externos litterarum commercio sibi adiunctos receperunt. Huius nomine inter Doctores nostros inscripto monstrabit profecto Academia nostra se

memorem esse quantum et doctrinæ et hominum utilitatibus Astronomiæ scientia profuerit.

In Arturo Willelmo Rücker ornando Academia nostra honore prosequitur alumnum suum, virum in docendo in rebus administrandis in rerum natura cognoscenda præclarissimum. Huius laudes agnovit Collegium Aenei Nasi, cuius olim scholaris erat, cum eum inter Socios honoris causa adsclsceret: agnovit etiam Societas Regalis quæ duodeviginti abhinc annos Sodalem creatum numismate etiam regio pro singularibus meritis donavit. Huic de tenuissimarum bullarum natura subtiliter quærenti contigit ut de magnitudine et ratione primarum illarum atomorum e quibus, ut antiquitus docuit Lucretius, omnis materia rerum constat, ipse multa reperiret, res altissimis tenebris abditas luce quadam scientiæ patefaceret et illustraret. Hic etiam de vi magnetica qua orbis terræ animatur peritissime disseruit, et insularum Britannicarum descriptionem magneticam denuo faciendam curavit. Neque ei satis erat ut Naturæ arcana ipse reseraret: idem, cum Britannicæ Societatis conventui præesset, contionem habuit luculentissimam de ratione quæ intercedat inter sententias philosophorum et physicorum de materia rerum docentium, quæ effecit ut multi de hac re loquerentur, plures cogitarent: idem in Regio Scientiæ Collegio Professor physicorum et in docendo et in rerum gubernatione summa laude inclaruit: eodem denique Secretario Societas ipsa Regalis tanquam in dapem omnium virorum doctorum naturam rerum ubique indagantium symbolam maiorem contulit. Hic vir tam impiger tamque ingeniosus qui omni hominum societati, quæ eo duce et auctore usa est, laudem et felicitatem semper attulit, nunc Academiæ Londinensi denuo constitutæ primus Præfectus latiorem profecto campum inventurus est in quo virtutes eius excurrant et cognoscantur.

CAMBRIDGE.—Prof. A. R. Forsyth, F.R.S., has been appointed a governor of University College, Liverpool, and will represent the University of Cambridge at the Abel Centenary to be celebrated in Christiania next September.

Mr. G. B. Mathews, F.R.S., senior wrangler 1883, has been re-elected to fellowship at St. John's College. At the same college Mr. J. H. Vincent, D.Sc. London, has been elected to a Hutchinson studentship for research in physics.

Mr. W. N. Shaw, F.R.S., secretary of the Meteorological Council, has been admitted to the degree of Doctor of Science.

The late Rev. Henry Latham, master of Trinity Hall, is succeeded in the mastership by Mr. E. A Beck, senior tutor. The late master has left some 17,000*l*. to the University to form a benevolent fund, from which grants, annual or occasional, may be made to members of the University who are incapacitated for their academic duties by age or infirmity, and to their widows and families when these have been left inadequately provided for.

The complete degree of M.A. *honoris causa* has been conferred on Mr. T. H. Middleton, the new professor of agriculture. In presenting him the public orator referred to the short stay of Prof. Somerville, his predecessor in office, and added "Studiorum academicorum in provincia tam nova occupanda, speramus professorem nostrum novum iuventutis nostræ ingeniis excolendis multo plus quam biennium esse impensurum."

MR. G. W. RUNDALL, head master of the High School, Newcastle-under-Lyme, Staffs., from 1891 to 1900, has been appointed Registrar of the Teachers' Registration Council, Board of Education.

MR. M. J. R. DUNSTAN, director of the Midland Agricultural and Dairy Institute, and director of technical instruction to the Notts County Council, has been appointed principal of the South-Eastern Agricultural College, Wye, in succession to Mr. A. D. Hall, who was recently appointed director of the Rothamsted Experiment Station.

THE Storey Institute of Science and Art at Lancaster was given to the town by the late Sir Thomas Storey to commemorate the jubilee of Queen Victoria. But though excellent work has been done in the Institute it has been handicapped in recent years by the want of accommodation for the technical and secondary departments. The handsome coronation gift of 10,000*l*. which Mr. Herbert L. Storey has just placed at the disposal of the Corporation of Lancaster, for the purpose of erecting a technical school on a site adjoining the Institute, will make a desirable educational development possible. Wealthy men in other centres should emulate Mr. Storey's public-spirited action.

THE Hartley Institution, Southampton, which has just been added to the list of University Colleges, and will in future be styled the Hartley University College, was founded in 1850, and has in recent years been greatly improved as a centre of scientific influence. The Institution is at present regulated by a scheme established by the High Court of Chancery in 1859 as altered or supplemented by eight schemes of the Charity Commissioners. The movement for the formation of a University College has been enthusiastically supported locally, and as soon as it became known that H.M. University Commissioners had pronounced the local University income to be 600*l*. short of the required 4000*l*. per annum, three gentlemen, interested in the College, combined together to supply the deficiency for this year, and the governing body was assured that the income should be maintained at the required sum in the future if a portion of the Treasury grant to University College was allotted to the Hartley University College. The College is primarily intended to provide the residents in the counties of Hampshire and the Isle of Wight, Dorset and Wilts with higher education, and is admirably situated geographically for that purpose. The south of England is generally supposed to be deficient in educational enterprise, and this is an additional reason why the activity which is being displayed by Southampton in the formation of this College should be welcomed by all those interested in education. It is felt that the present buildings of the Institution are inadequate for the growing number of students, and a movement is on foot for raising a sum of 100,000*l*. to enable the University College to be suitably housed. It is hoped that a beneficent millionaire will be found willing to interest himself in the scheme, and help in supplying a great deficiency in the educational equipment of the south coast. The principal of the college is Dr. S. H. Richardson.

ON June 25, in the House of Commons, the consideration of the Education Bill in Committee was resumed on the second clause, which empowers the new authorities to make provision for higher education. From the *Times* report, we learn that an amendment was moved with the object of introducing words defining the duties of the education authorities, and directing them to supply secondary, technical and higher education, and to provide for the organisation and coordination of all forms of education, including the training of teachers. It was not accepted by the Government, but a compromise was arrived at; and it was agreed that the authorities should take such steps, after consultation with the Board of Education, as might seem desirable to secure the training of teachers and the general coordination of education. An amendment was carried providing that the funds colloquially known as whisky money should be used without deduction by the county councils in promoting higher education. On Monday the Bill was again before Committee of the House. A proposal that the county boroughs should be exempted from the operation of the provision which restricts to 2*d*. the amount of the rate leviable for higher education was accepted by the Government. An amendment was brought forward empowering the Board of Education to authorise the county councils to strike a rate exceeding 2*d*. The clause gives the Local Government Board the right to increase the rate by provisional order on the application of a county council. Objection was made to this clause, and after discussion it was decided to dispense with the elaborate machinery of provisional orders and to substitute for it the simple assent of the Local Government Board to a proposed extension of the 2*d*. rate. The limit to the rating power for secondary education has thus been abolished entirely for county boroughs and conditionally for rural counties. Passing to the third clause, which proposed to give to the councils of boroughs with a population of more than 10,000 and to the councils of urban districts with a population of more than 20,000 the right to levy a penny rate for the purpose of supplying higher education, an amendment was agreed to on Tuesday conferring the same right on all non-county boroughs and urban districts. Another amendment which would have given non-county boroughs and urban districts unlimited rating power was negatived. After further discussion it was agreed that the clause as amended should stand part of the Bill.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 12.—"On the Parasitism of *Pseudomonas destructans* (Potter)." By M. C. Potter, M.A. F.L.S., Professor of Botany in the University of Durham College of Science, Newcastle-upon-Tyne. Communicated by Sir Michael Foster, K.C.B., Sec. R.S.

The author gives an account of his further study of the action of the cytase and toxin, secreted by this bacterium, upon the living turnip cell; and he has succeeded in tracing the passage of the bacterium into the cells, through the cell-wall. The observations were made from pure cultures, under the most rigid sterile conditions, by means of the hanging drop. The action of the cytase and toxin was surprisingly rapid; the swelling of the cell-wall and contraction of the protoplasm could be observed almost immediately, upon the introduction of the Pseudomonas. Within an hour and a half the cell was dead and its walls in an advanced stage of disintegration. The original cell was kept under observation for some days, and after patient and continuous watching certain of the bacteria were observed slowly forcing their way through the wall, until finally they emerged into the cell-cavity. The penetration of the wall was observed on several occasions, and numerous individuals could be seen in all stages of the process. The time required varied with the thickness of the wall, but on an average occupied about three hours.

Important evidence of the perforation of the cell-wall by *P. destructans* was also afforded by the method of paraffin sections; by fixing and double staining, the cell-wall and bacteria were distinctly differentiated, the latter being shown fixed in the actual process of perforating the wall, and various stages of penetration could be distinguished.

Experiments showed that the old and fully developed cuticle is apparently proof against the action of the enzymes excreted by *P. destructans*, but this parasite can readily effect an entrance into its host through the undeveloped epidermis of young and tender structures.

A comparison of the parasitism of *Botrytis cinerea*, as demonstrated by Nordhausen, presented an exact parallel. The point was established that this bacterium has the power of destroying the living cells of the turnip, and, subsisting upon their dead contents, continues to work its way through the host, and it thus acts in precisely the same manner as one acknowledged parasitic fungus.

Chemical Society, June 18.—Elimination of a nitro-group on diazotisation. Dinitro-*p*-anisidine, by Prof. Meldola and Mr. J. V. Eyre. When dinitro-*p*-anisidine is diazotised in presence of hydrochloric acid the 3-nitro-group is replaced by chlorine.—Preliminary notice of some new derivatives of pinene and other terpenes, by Prof. Tilden and Dr. H. Burrows. Pinene nitrosochloride, when treated with potassium cyanide in alcohol, is converted into pinene nitrosocyanide, a colourless crystalline substance melting at 171°. The latter reacts readily with various reagents, furnishing well-crystallised reaction products.—The colour-changes exhibited by the chlorides of cobalt and some other metals from the standpoint of the theory of electro-affinity, by Messrs. Donnan and Bassett. These colour-changes are shown to be due to the gradual dissociation of the complex molecules of the salts.—The stereochemical formula of benzene, by Mr. Marsh. A discussion of the various possible space formulæ of benzene and a reply to Graebe's objections to the stereocentric representation.—An accurate method of determining the compressibility of vapours, by Dr. Steele. A description of a special apparatus devised for this purpose.—A new type of substituted nitrogen chlorides, by Dr. Chattaway. The author describes a group of these substances containing three negative radicles directly attached to the nitrogen atom, such as dibenzoyl nitrogen chloride, $(C_6H_5CO)_2$:N.Cl.—The preparation of pure chlorine and its behaviour towards hydrogen, by Messrs. J. W. Mellor and E. J. Russell. The chlorine was prepared by electrolysis of fused silver chloride, and the hydrogen by the action of steam on sodium. Mixtures of these gases were found to be exploded by electric sparks even after several months' drying over phosphorus pentoxide.—Derivates of dibenzoyl mesitylene, by Mr. W. H. Mills and Dr. Easterfield.—The molecular condition of borax in solution, by Mr. H. S. Shelton. The author, from a series of measurements of electric conductivity of borax solution of diminishing concentrations, shows that hydrolysis into boracic acid and sodium hydroxide occurs to the extent of 4 per cent. at 25°.—On the union of hydrogen and chlorine, v. and vi., by Dr. Mellor. The author concludes that the chemical change occurring when moist chlorine is exposed to sunlight is due to interaction between the chlorine and the moisture contained in it. No intermediate compound, such as hypochlorous acid or chlorine monoxide, seems to be formed.—On some hydroxy-pyrone derivatives, by Messrs. Tickle and Collie. A description of hydroxydimethylpyrone and hydroxycomenic acid obtained by oxidising dimethylpyrone and meconic acid respectively with hydrogen peroxide.—The absorption spectra of phloroglucinol and some of its derivatives, by Messrs. Hartley, Dobbie and Lauder. The absorption spectra of phloroglucinol and its trimethyl ester are almost identical, whence it follows that the parent substance possesses an enolic structure.—Solubility of mannitol, picric acid and anthracene, by Dr. Findlay. An investigation of the general applicability of the rule recently observed by the author connecting the solubilities of substances.—Menthyl formylphenylacetate, by Messrs. Cohen and Briggs. A description of the principal properties of this substance is given differing in some points from those assigned to it by Lapworth and Hann.—Transformation of diacetanilide into aceto-*p*-aminoacetophenone, by Dr. Chattaway.—Nitrogen chlorides and bromides derived from *ortho*-substituted anilides, by Dr. Chattaway and Mr. Wadmore. A description of several members of this class obtained by the interaction of hypochlorous and hypobromous acids with the corresponding anilides.—Substituted nitrogen chlorides containing the azo-group, by Dr. Chattaway.—The action of chlorine and bromine on nitroaminobenzenes, by Dr. Orton. A description of *sym.* trisubstituted chloro- and bromonitroaminobenzenes obtained by the interaction of the above substances.—The transformation of diazoamido- into aminoazo-compounds and of hydrazobenzene into benzidine, by Dr. Chattaway. A new method of formulating these changes is suggested.—Tribromophenolbromide, by Mr. E. W. Lewis. The melting point of this substance when pure is 148°, not, as generally stated, 118°.

Royal Astronomical Society, June 13.—Dr. J. W. L. Glaisher, president, in the chair.—M. Bigourdan gave an account of the long series of observations of nebulæ which he is making at the Paris Observatory, his aim being to obtain accurate micrometric measures of a large number of nebulæ. M. Bigourdan presented to the Society two volumes of his observations, and also the volume of Pingré's "Annales Célestes," which the author had left in MS., and which M. Bigourdan had now edited and published.—Dr. Downing read a paper on the distribution of the stars in the Cape Photographic Durchmusterung. He had reduced the places of the stars to galactic coordinates, to investigate their distribution with reference to the Galaxy. The results showed a ring of bright stars nearly in the Galactic plane, stars in the groups mag. 6·5 to 7·0 being more uniformly distributed. After magnitude 8·0 there is a greater difference between the density of the polar and equatorial zones of the Galaxy. The Cape Durchmusterung agrees with the Bonn Survey in assigning an ellipsoidal form to the visible universe.—Mr. Thackeray read a paper on a comparison of Groombridge's and Struve's right ascensions of close circumpolar stars, prefacing it with an account of the life of Stephen Groombridge. The paper was accompanied by a table showing, from an independent comparison of a certain number of Groombridge's stars, that the probable error of an observation is about 0s. ·053.—Mr. Filon read a paper on reduction of measures of Swift's comet (*a* 1899) from photographs taken with a portrait lens of 30-inch focus and 5-inch aperture. Apart from the intrinsic value of the comet places, it appeared of interest to determine the degree of accuracy obtainable from measures of stars on plates taken with an ordinary portrait lens, and to find if photographs thus taken would repay the labour of measurement and reduction. The author concluded that such plates can give star places accurate to about 0″·83 of arc.—Mr. Hinks read a paper on the reduction of photographs of Eros for the determination of solar parallax. He concluded that the direct comparison of simultaneous photographs by linear reductions is the most convenient method. He desired to propose that seven or eight observatories, spread over as long an arc of longitude as possible, should agree upon a common list of comparison stars, and measure all their plates taken within a period of nine days. It might then be possible to find out in two or three years whether Eros will give as good results for parallax as other less favourably situated minor planets.—A paper by Mr. H. C. Plummer, on the principle of the arithmetic mean, and other papers, were taken as read.

Geological Society, June 11.—Prof. C. Lapworth, F.R.S., in the chair.—A descriptive outline of the plutonic complex of Central Anglesey, by Dr. Charles Callaway. The central complex of Anglesey was originally composed of diorite, felsite and granite. The gneiss and granitoid rock of the area, formerly regarded as sedimentary in origin, are now known to be plutonic masses.—Alpine valleys in relation to glaciers, by Prof. T. G. Bonney, F.R.S. The author discusses some hypotheses about the formation of Alpine valleys which have been advanced by Prof. W. M. Davis, but has left the Ticino Valley, on which the latter lays much stress, to Prof. Garwood, who has very lately visited it. Prof. Davis maintains that the upper and wider parts of Alpine valleys were excavated in pre-Glacial times, the lower and narrower portions during the Great Ice Age. The author tests this hypothesis by applying it first to the valley of the Visp, of the eastern arm of which, and of the "hanging valley" like a gigantic corrie, where Saas Fee is situated, he gives a description, pointing out that all parts are so connected that any separate explanation of their form is impossible. To obtain an idea of the condition of the Alps in Middle and Later Tertiary times, we may consider the effect of alterations of temperature, on the assumption (which, as he shows, is not likely to be seriously incorrect) that the altitude of the Alps during the greater part of their existence has remained unchanged. A rise of temperature of from 6° to 7° F. would have the same effect as lowering the district by 2000 feet; a rise of 10° would correspond with 3000 feet. In the latter case the Pennine chain about the headwaters of the Visp would be comparable with the range from Monte Leone to the Ofenhorn. With a rise of 14° glaciers would almost vanish from the Alps, for the snow-line would then be at 12,000 feet above sea level. Thus glacial action in the Oligocene and Miocene ages would be a negligible quantity, and it would gradually become sensible during the Pliocene; but glaciers would not invade valleys now free from them until the temperature was some degrees lower than it is at present—in other words, can have only occupied these during a small portion of their existence. The author passes in review a number of other Alpine valleys, which lead to the same conclusion. He calls attention once more to the connection of cirques with valleys, to the impossibility of referring the former to glacial action, and to the unity exhibited by all parts of the Alpine valleys, touching upon some structural difficulties which Prof. Davis has been content to meet with hypotheses. Alpine valleys in all parts, as the author shows, indicate by their forms meteoric agencies other than glaciers, which can only have acted for a comparatively short time and have produced little more than superficial effects.—The origin of some "hanging valleys" in the Alps and Himalaya, by Prof. E. J. Garwood. Lateral valleys which enter the main valley marked by discordant grades in the Jongri district of the Sikhim Himalaya have been attributed by the author to Pleistocene elevation and super-erosion of the main valley by water. Similar valleys in the Val Ticino have recently been attributed to overdeepening of the main valley by ice. The author shows that there is no real proof of this, in fact the evidence seems strongly to point to fluviatile and not glacial erosion of the main valley. This is shown by the overlapping profiles and river-gorges situated both above and below some of these "hanging valleys," and by the fact that a greater relative amount of erosion has taken place towards the upper end of the main valley than at the lower, where the mouths of the "hanging valleys" are less elevated.

Zoological Society, June 3.—Dr. Henry Woodward, F.R.S., vice-president, in the chair.—Mr. Lydekker exhibited the mounted head of a male Siberian wapiti, and made remarks on the various forms of the wapiti met with in northern Asia.—Mr. G. A. Boulenger, F.R.S., exhibited a strap made of the skin of the okapi (*Okapia johnstoni*), which had been received in Belgium from the Mangbetta country (lat. 30° N., long. 28° E.) in December, 1899, a year previous to the arrival in this country of the two bandoliers upon which the name *Equus johnstoni* had been founded.—Dr. Forsyth Major exhibited a reduced photograph of the skin of a female okapi (*Okapia johnstoni*), recently received by the Congo State Museum at Brussels, together with the skeleton of a male. Dr. Forsyth Major also made some remarks on this material, which had been handed over to him for publication.—Mr. E. J. Bles exhibited and made remarks upon some living tadpoles of the Cape clawed frog (*Xenopus laevis*). This species had bred in the Society's Gardens, and the event had formed the subject of a paper in the Society's *Proceedings* by Mr. F. E. Beddard (*cf. P.Z.S.* 1894, p. 101), but Mr. Bles was able to supply some additional particulars.—Mr. Lydekker described the head and skin of a wild sheep from the Thian Shan, recently presented by Mr. St. George Littledale to the British Museum, as belonging to a new subspecies, which he proposed to call *Ovis sairensis littledalei*. He also exhibited and described a specimen of the sheep named by Severtzoff *Ovis borealis*, which had been brought home by Mr. Talbot Clifton from the Yana Valley.—A communication was read from Dr. R. Broom containing an account of the differences exhibited in the skulls of Dicynodonts from the Karroo deposits of South Africa. The author was of opinion that these differences, in many cases, were not specific, but were due to sex, and, consequently, that many of the specimens which had received specific rank really belonged to the same form.—Mr. F. E. Beddard, F.R.S., read a paper on the gonad ducts and nephridia of the annelid worm Eudrilus, in which supplementary facts to those already ascertained by previous authors concerning these organs were adduced.—Dr. C. I. Forsyth Major read a paper on the pigmy hippopotamus from the Pleistocene of Cyprus, in which he described the fossil remains of *Hippopotamus minutus*, Blainv., exhibited by the author at the meeting of the Society on April 15. The characteristic features of this primitive hippopotamus were pointed out, and reasons were given for the assumption that the type-specimens of the species, Cuvier's *Petit Hippopotame fossile*, supposed to have been found near Dax in the Landes, had been brought over from Cyprus.—Mr. Hamilton H. Druce contributed a paper containing remarks on several species of butterflies of the family Lycænidæ from Australia, especially in reference to those described by Herr Semper. He also read descriptions of several apparently new species of the same family from the Eastern Islands and from Africa.—Mr. R. I. Pocock read a paper which dealt with the habits of the littoral spiders belonging to the genus Desis. The seven known species were enumerated, and one of them was described as new, under the name *Desis kenyonae*.—Mr. H. R. Hogg contributed a paper which contained additional information concerning the Australian spiders of the suborder Mygalomorphæ. Out of a collection of forty specimens (comprising examples of eleven species and nine genera) received by the author, no less than nine species and five genera had proved to be new, and were described in this paper.

EDINBURGH.

Royal Society, June 2.—Dr. Ferguson in the chair.—Prof. Metzler communicated a paper on some identities connected with alternants and with elliptic functions, in which it was shown that an identity established by Cayley and discussed by Muir, and believed by them to be of general validity, was not true in a particular set of cases.—Prof. A. Smith read a paper on amorphous sulphur and its relation to the freezing point of liquid sulphur. He showed that the freezing point, which in books is stated to be very variable within certain limits, was determined by the amount of amorphous sulphur present. When the amount of amorphous sulphur present was plotted against the freezing point an almost perfect straight line was obtained, indicating 119·25 as the freezing point of liquid sulphur quite free from the amorphous form, although practically that had never been obtained. Taking this value and estimating the depressions of the freezing point due to the presence of the amorphous sulphur, he calculated the molecular depression by means of van 't Hoff's formula and finally found 7·6 as the estimated molecular weight of amorphous sulphur—a value which under the difficulties of the experiment was a good approximation to 8.—Dr. W. Peddie, in a paper on the use of quaternions in the theory of screws, &c., showed how by a new interpretation of the scalar and vector parts of a quaternion a screw could be completely symbolised, and the whole theory developed in a compact and systematic way. The direction of the axis of the screw was determined by the direction of the vector part of the quaternion, and the scalar part of the quaternion represented the associated translation, the pitch being the ratio of the scalar to the tensor of the vector part. Any quaternion so regarded represented a screw through the origin; but the same quaternion could be made to represent a screw with axis not passing through the origin by breaking up the vector part into two portions, one of which represented the displacement, while the other represented the axis and with the scalar gave the pitch.—Dr. Hugh Marshall contributed a short paper on the dissociation of the compound of iodine and

thiourea, in which it was shown that in aqueous solutions of the compound there appears to be a complex balanced action of the kind represented by the equations

$$2CSN_2H_4 + I_2 \rightleftharpoons (CSN_2H_4)_2I_2 \rightleftharpoons (CSN_2H_4)_2^{\cdot\cdot} + 2I'.$$

The addition, to such a solution, of any substance which diminishes the ionisation results in increased dissociation, as shown by the increased intensity of the colour of the solution.

PARIS.

Academy of Sciences, June 23.—M. Bouquet de la Grye in the chair.—New researches on batteries founded on the reciprocal action of two liquids, by M. Berthelot. The smallest amount of hydrogen visible in a voltameter of special form after one minute was determined for pressures of 760 and 5 mm., in the latter case 0·000014 mgr. This sensitive voltameter was then applied to the determination of the minimum electromotive force required to produce visible decomposition, and to measure the effects produced by liquid batteries.—The properties of a certain anomaly which is capable of replacing the anomalies already known in the calculation of the disturbances of the minor planets, by M. O. Callandreau.—The influence of the photographic magnitude of stars upon the scale of reduction of a negative, by M. Prosper Henry. Instead of comparing the results obtained by eye and photographically as has been proposed by Gill, a purely photographic method is here suggested. A portion of the sky is photographed upon a given plate first with a short exposure and then with prolonged exposure, the pointer micrometer having been slightly displaced between the two exposures. The results of the application of this method with the large objective of the Paris Observatory are now given.—The extension of the kathode hypothesis to nebulæ, by M. H. Deslandres. The light emitted by nebulæ has been attributed by Arrhenius to electrified particles, by Nordman to Hertzian waves, but the author regards both these explanations as inadmissible, since, for the same reason, the earth's atmosphere at night should glow with an equal lustre. The kathodic hypothesis appears to offer a better explanation.—On algebraic continued fractions, by M. R. de Montessus de Ballore.—Researches on actino-electric phenomena, by M. Albert Nodon. When light rays or ultra-violet rays are thrown upon a thin conducting plate they give rise, on the dark face of this plate, to radiations analogous to X-rays. They differ from kathode rays, since they easily pass through metals and black paper, and appear to possess properties intermediate between X-rays and radium rays.—On a phenomenon observed on an excitor, the spheres of which are connected to a Ruhmkorff coil, by M. H. Bordier.—The effect of self-induction on the ultra-violet portion of spark spectra, by M. Eugène Néculcéa.—On the heats of dilution of sodium sulphate, by M. Albert Colson.—The chlorinating properties of a mixture of hydrochloric acid and oxygen, by M. Camille Matignon. Gold, tellurium and platinum are attacked by a mixture of oxygen and pyrochloric acid at temperatures much below the temperature of reaction between hydrogen chloride and oxygen. The mixture may in certain cases replace chlorine.—On the acidity of pyrophosphoric acid, by M. H. Giran. By a study of the heats of neutralisation and heats of solution of the sodium pyrophosphates, the conclusion is drawn that pyrophosphoric acid is a tetrabasic acid, the acid value of each of the hydroxyl groups being identical.—The displacement of strong bases by ammoniacal copper oxide, by M. Bouzat. On the phenyl migration of phenylethylene and its derivatives, by M. M. Tiffeneau. Evidence is given showing that in several instances the migration of the phenyl group is probable.—Study of the action of selenyl chloride upon erythritol, by MM. C. Chabrié and R. Jacob.—On dibenzoylhydrazobenzene, by M. P. Freundler. MM. Biehringer and Busch have recently described a new mode of decomposition of diazo-compounds by means of copper powder, in which dibenzoyl-hydrazobenzene is stated to be formed. It is here shown that the compound really formed in this reaction is benzanilide, the benzoyl derivative of hydrazobenzene possessing entirely different properties.—Acyl derivatives of isopyromucic acid: the acetate, benzoate and pyromucate of isopyromucyl, by M. G. Chavanne.—Chemical analysis of *Piper Famechoni* or Kissi pepper, by M. A. Barillé.—On the phenomena of migration in ligneous plants, by M. G. André.—On the composition of ewe's milk, by MM. Trillat and Forestier.—On the estimation of organic nitrogen in water, by M. H. Causse.—Analysis of the mode of action of lecithins upon the animal organism, by MM. A. Desgrez and Aly Zaky.—Orthogonal skiagrams of the thorax; their use for the localisation of anomalies and for the measurement of organs, by M. H. Guilléminot.—The physiological secretion of the pancreas, by MM. C. Delezenne and A. Frouin.—Physiology of the heart in some colonies of compound Ascidians, by M. Antoine Pizon.—On the idea of depth applied to African metalliferous layers, by M. L. de Launay.—On the presence of Carboniferous strata in Tidikelt, Sahara, by M. G. B. M. Flamand.—Reproduction of some Palæolithic figures drawn on the walls of the grotto of Font-de-Gaume (Dordogne), by MM. Capitan and Breuil. Four reproductions are given, three of the bison and one of reindeer.—On the colouring matter used in the figures described in the previous paper, by M. Henri Moissan. The colours are ochres formed of the oxides of iron and manganese.—The cyclone at Javaugues (Haute-Loire), on June 3, 1902, by M. Bernard Brunhes.

CONTENTS.

THURSDAY, JULY 10, 1902.

THE RECORD OF HUXLEY'S SCIENTIFIC WORK.

The Scientific Memoirs of Thomas Henry Huxley. Vol. iv. Edited by Sir Michael Foster and Prof. E. Ray Lankester. Pp. 689; pls. 28. (London: Macmillan and Co., Ltd., 1902.) Price 30*s.* net.

THE present volume is the fourth of the promised series, and contains a collection of the scientific memoirs, addresses, and reviews, by Huxley, published throughout the period ranging from the early part of the year 1874 until his death. The first item reproduced is that on the skull and heart of Menobranchus, the last the masterly addendum to the life of Richard Owen, with the tenour of which our readers have long been familiar (NATURE, vol. li., p. 169). When it is said that the intervening memoirs include those on "Ceratodus and the Classification of Fishes"; on "The Craniofacial Apparatus of the Lamprey"; on "The Classification and Distribution of the Cray Fishes"; on "The Cranial and Dental Characters of the Canidæ" (with its prophetic passage on the future of the systematist); on "The Application of the Laws of Evolution to the Vertebrata" (than which Huxley never wrote a finer philosophic treatise); on "The Gentians" (which to the systematic botanists, headed by Hooker and the late Prof. Baillon, who heard it read, came as a surprise); and, finally, the last zoological paper which Huxley wrote, "Some further Observations on the Genus Hyperodapedon," it is evident that some of his very best work is in this volume brought before the reader.

By way of general comment, we need only say that the standard of the former volumes, upon which we have more than once passed favourable judgment, has been maintained, except, perhaps, that plates 1 to 3 have suffered somewhat, from the lack of blue-grey colour bestowed upon their originals.

In reviewing the volume which preceded the present one, we took occasion (NATURE, vol. lxiv., p. 76) to comment on the imperfection of the published list which the editors originally caused to be circulated in making their intentions known. We are pleased to find that of the three omissions to which we then more particularly drew attention, two have been made good, chief among them being the Survey memoir on "The Crocodilians of the Elgin Sandstones," which in the present volume monopolises seventeen of the twenty-eight plates provided. One omission upon which we dwelt they have passed over, viz. the Rede lecture on "Animal Forms," delivered at Cambridge in 1883 and duly reported in these columns (NATURE, vol. xxviii. p. 187); and we would remark that, if only on account of the absence of this, the words "THE END" with which the present volume closes cannot mark the completion of the editors' task, if justice is to be done to the life's record in science of the great man whose teachings the memorialists have decided to perpetuate.

To proceed, let it be said that, in addition to the omission just named there are at least six other of Huxley's scientific writings which we consider should have found recognition in the present volume. In seeking comparison with other published works dealing with Huxley's career, we naturally turn to the bibliographic record given in the "Life and Letters" by his son; and there we find duly listed addresses on "The Hypothesis that Animals are Automata and its History" and on "The Geological History of Birds," which our editors have either overlooked or withheld. The latter, a Royal Institution lecture, was first delivered in America and published in full in "American Addresses"; and it is significant that of the five addresses this book contains, the only one the present volume bears (*i.e.* that on "The Study of Biology") was reprinted elsewhere. The address on "Animals as Automata" was reported in NATURE (vol. iv. p. 362), and with elaboration was printed in "Science and Culture," side by side with the article on "Sensation and the Unity of Structure of the Sensiferous Organs," which our editors reproduce. We submit that both it and the three American addresses on "Evolution" should have been included in the present volume, since they give expression to the working of Huxley's mind on the realisation of a complete evolutionary series—*i.e.* the equine. About the Baltimore address, which the "American Addresses" volume also contains, opinions may differ.

Far more serious, however, is the omission, both from its proper place in vol. ii. and from the present volume, of the great Geological Survey memoir (decade xii.) bearing title "Illustrations of the Structure of the Crossopterygian Ganoids," which, with the Rede lecture aforementioned, is not listed in even the "Life and Letters"; and we are at a loss to conceive by what process other than a too exclusive reliance upon the Royal Society Catalogue of Scientific Papers (which for the period concerned is defective) this oversight, resulting in the omission of one of the most important and far-reaching memoirs Huxley ever wrote, can be explained, especially when it is seen that the editors have duly incorporated its preliminary correlate in its proper place.

Nor is this all. Huxley's lecture before the Fisheries Exhibition at Norwich in 1881 is duly reproduced, but why not that of 1883, which marked the opening of the congresses of the Exhibition at South Kensington, perhaps the more important of the two? This omission is the more unfortunate, since, in the hands of Prof. McIntosh, the chief conclusion reached has but lately become the leading theme in rival controversy among fishery experts. And it is pertinent to this to remark that the memoir on the Belemnitidæ, to which we alluded in reviewing vol. iii., and which at the outset escaped recognition, similarly contains the striking observation that the genus Belemnites, if a Decapod, is numerically deficient in "arms," and that this but a month or so ago, in the hands of Huxley's pupil Crick, has led to a startling generalisation, which we can personally confirm.

The editors announced in their original prospectus 151 contributions in all—they have printed 163. In doing so they have shown themselves to have been originally lacking by twelve. We have shown that others have yet to be reprinted, if the work is to be "complete" as was originally resolved, and to depict worthily the scientific labours of the great man whose reputation in the domain

of "exact science" is (according to our editors' preface) in danger of being underrated.

Moreover, it becomes a question whether the memoir on the "Oceanic Hydrozoa" should not be incorporated, to ensure absolute completeness. We are quite aware that the editors, in their preface, give reasons for excluding this; but we venture to think that if, when they took this step, they had realised the extent of the Survey memoir on the Elgin Crocodiles, and had reflected that the memoir on "The Development of the Elasmobranch Fishes," despite its bulk, was incorporated in the volumes memorialising the late Francis Maitland Balfour, they might perhaps have acted otherwise.

There are thus a possible series of six or seven important scientific communications to be yet reprinted, in order to justify the fulfilment of the memorial. As the matter stands a supplementary volume is imperative, and we leave the plea for it, with respect and full assurance, in the publishers' hands.

The frontispiece to the present volume is a highly successful photographic reproduction of the obverse of the Huxley Memorial Medal. As a likeness it transcends the statue; and it affords us pleasure to remark that the artist (Mr. F. Bowcher) who produced the model is at present engaged upon an enlargement of it, which promises to be even more true to life, and is to be mounted in the Town Hall at Ealing, the place of Huxley's birth. G. B. H.

GEOLOGICAL HISTORY.

History of Geology and Palaeontology to the End of the Nineteenth Century. By Karl Alfred von Zittel. Translated by Maria M. Ogilvie-Gordon., D.Sc. London, Ph.D. Munich. Pp. xiii + 562. (London: Walter Scott, Ltd., 1901.) Price 6*s*.

WHAT may be called the archæological side of the history of this science has been often treated; but what has long been needed is such a history that the serious student can ascertain exactly the position of any branch at the present day, and the more important steps in the advance towards its position. For a task requiring such a wide range of knowledge and such a well-balanced and unbiassed mind there is probably no one better fitted than Prof. von Zittel, while to translate, condense and adapt the work to the needs of British readers has been a congenial duty to one of Zittel's own talented pupils, Mrs. Ogilvie-Gordon.

The author, judging from his preface, is himself in doubt as to the possibility of combining the difficult task of writing a work which will satisfy the specialist and also commend itself to every man of culture. Frankly we think that to do this is impossible; the needs of the two types of readers are so wholly distinct. For even the best class of popular readers something different from the steady and level plod through division after division of the subject is required. There must be what might be called "picture-writing," colour, shading, prominence, gradation, grouping, and above all perspective. Without these the non-technical reader cannot see wood for trees; he has no landings on which to pause for breath, and, worst of all, he hardly realises when he has attained a summit and obtained a view.

But, cutting adrift the man of general culture, what is there here for the specialist? There is a most conscientious, concise, complete, and well-balanced record of the chief steps forward in each of the numerous branches of a complex subject, perfect fairness in the treatment of the different workers and of the claims of various nationalities, a remarkable clearness in indicating the general advance of the science as a whole while treating of its many subdivisions, and a powerful presentment of the significance of the inauguration and final proofs of the chief principles of geology.

About a quarter of the whole work is devoted to geological knowledge in the ages of antiquity, the beginnings of palæontology and geology, and the "heroic age" of geology (1790-1820). Under the first head we read that "fanciful hypotheses and disconnected observations cannot be acknowledged as scientific beginnings of research"; the next stage brings us to the first mineral maps and sections, the earliest ideas of mineral succession, and to primitive opinions about fossils and volcanoes. The "heroic age" was the time of Werner and Hutton, von Buch and Humboldt, Kant and Laplace, Cuvier and Buckland, and above all of William Smith. We are thus brought to the beginning of the nineteenth century, and henceforward we follow the development of the science under the following heads:—Cosmical Geology, Physiographical Geology, Dynamical Geology, Petrography, Palæontology, and Stratigraphical Geology.

The treatment of these branches is singularly even, the weakest, perhaps, being the first and last, while for the strongest it is difficult to choose between the dynamical, petrographic and palæontological sections. The translator has shifted the position of the stratigraphical section and omitted that on topographical geology, we think wisely; and she has also shortened the work, partly by abridgment and partly by omission. This difficult task has been discharged with considerable skill and discretion, though we might, perhaps, be inclined to cavil at some of the omissions; for instance, the suppression of the "kern theory" of Rosenbusch and the rock-formulæ of Michel-Lévy, to note only two examples.

One characteristic of some of the heroes of geology seems not to have died out at the present day. We read that

"It was the spoken word of Werner that carried. Of written words no man of genius could have been more chary. His dislike of writing increased as he grew older, . . ."

Again,

"Hutton's thoughts had been borne in upon him direct from nature; for the best part of his life he had conned them, tossed them in his mind, tested them, and sought repeated confirmation in nature before he had even begun to fix them in written words, or cared to think of anything but his own enjoyment of them."

And once again,

"a dinner was arranged . . . and William Smith *consented to dictate* a table of the British strata from the Carboniferous to the Cretaceous formation."

Zittel is seen at his best when dealing with the classical works of those masters of the science who have given us

its greater principles. The laws enunciated by such men as Suess, Heim, Richthofen, Sorby, Brögger, Lehmann, Smith, Sedgwick and Darwin are given with genuine appreciation and generally illuminated by a brief but telling thumb-nail picture of their lives and achievements.

The translator, while suppressing too great detail in foreign work, has helped English readers by fitting into its place the occasionally omitted work of English-speaking geologists (see pp. 358, 360, &c.). This plan might with advantage have been extended; for instance, the work of Milne and Davison on earthquakes, of Allport, Bonney and Phillips on petrology, and of Ramsay and Topley in the connexion of geology and geography, might well have received fuller notice; and the application of geology to economic questions still demands its historian, who would have many a strange tale of failure and success to tell.

While the chapter on petrography gives the reader a good summary of the chief theories enunciated, the stages of their proof and their significance in the progress of the science, the palæontological section, probably from the magnitude of the subject, is not so instructive, and does not succeed in giving the reader a clear picture of the real meaning of the successive discoveries made.

Again, the stratigraphical chapter is at the same time one of the most difficult to treat fairly, and the one which is least balanced in its treatment. The introductory part, while giving considerable weight to discoveries in palæophytology, is admirable in picking out the chief contributions to palæontology as applied to stratigraphy, and in its pronouncement upon such subjects as the Sedgwick-Murchison controversy. But the detailed portion gives less than three pages to the Devonian system, omits all account of the zoning of the earlier Palæozoic rocks, and then proceeds to devote almost forty pages to the Trias.

The translator's work has been carefully and conscientiously done, and the book reads far better than is usually the case with translations. A few slips or misprints are unavoidable, and here and there an ambiguity of expression has crept in. We read *Jorulla* (66), physician (77), Linnæus (for *limnaea*, 104), on the age of the human race (the antiquity of man, 195), Davis (David, 253), Euganian Isles (259), microscopic (macroscopic, 369), and aquo-igneous, for which we would venture to suggest the less cacophonous hydrothermal.

The publisher is evidently under the impression that the severer form of the German original requires tempering to that shorn lamb the British reader. The translation has been alleviated by portraits of eminent geologists, many of them admirable and some new. Those of Suess and of Zittel are excellent, but we can hardly bring ourselves to believe that that of Hutton is lifelike. Then, in addition to the shortening of some of the drier details, we have the wholesale omission of the bibliographies which accompany each chapter and many sections of the original. We hope and believe that this is a mistake. It is the serious student who will consult this work; to him the bibliographies are essential, and this will drive him to the original. In some future edition we hope to see these restored, and when this is done we would suggest that even the specialist is deserving of, and will certainly be grateful for, anything which helps to pilot him quickly and safely to the haven of his inquiries. Such aid as author and printer can give are his right. The solid mass of print should be broken up by the use of more sections and headings, italics and black-faced type, and above all good headlines to the pages (as in the original), so that a man in search of particular information may find it with the least possible expenditure of time and temper.

But all geologists are grateful to Prof. Zittel for his thorough and painstaking labour, for his fairness and breadth of view, and for his wonderful grasp of the whole of his science; and English-speaking geologists are under an especial debt of gratitude to Mrs. Ogilvie-Gordon for her timely, accurate, and well-written translation.

PLANE SURVEYING.

Plane Surveying. A Text and Reference Book for the Use of Students in Engineering and for Engineers Generally. By Paul C. Nugent, A.M., C.E., Associate Professor of Civil Engineering, Syracuse University. Pp. xvi + 577. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1902.) Price 14*s*. 6*d*.

THIS book treats of that elementary part of the subject of surveying, especially useful to engineers, which deals generally with surveys of small areas on large scales. Any book on the subject which comes from America is worthy of attention, since American practice differs in many respects from ours, and this text-book is useful for the purpose of comparative study.

Amongst the subjects dealt with are linear measuring instruments and the measurement of lines, chain surveying, compass surveying, levelling, transit surveying (*i.e.* the use of the theodolite), topographical, hydrographic and mine surveying, and U.S. Government large-scale surveys and resurveys. There are also chapters on the theory of telescope construction, the planimeter, the slide rule and the solar instrument (sun compass), and an appendix on photo-topographic methods.

We have a good deal to learn from America in the use of steel tapes, which for many surveying purposes should supersede the chain, and some useful information on the question will be found at the beginning of the book. The method here described of cutting up the ground in a chain (or tape) survey differs from the English system, and the latter is preferable. A great deal of space is given to surveying with the compass: indeed too much space considering the essential inaccuracy of all compass methods; and on the other hand but little is said about triangulation with a theodolite or traversing with the same instrument, subjects which each deserve a chapter to themselves.

In the chapter on topographical surveying we have topographical methods described from the engineering surveyor's point of view, and for certain large-scale engineering topographical surveys the methods mentioned are useful. But they are not generally the methods used by surveyors on regular topographical surveys, such as the topographical branches of the Survey of India or the U.S. Geological Survey, and the description given of the

use of the plane-table as a topographical instrument is inadequate.

About a dozen pages are devoted to hydrographic surveying, and it is no doubt desirable that the engineer should have a bowing acquaintance with the subject, mainly to enable him to carry out the survey of small inland waters. If he had a larger task on hand, he should consult one of the recognised treatises on the subject.

In a book on surveying written by a professor of engineering it is remarkable that there is so little mention of the execution of special surveys for engineering purposes, such as railway and canal surveys. The whole theory of plane surveying is so simple that the engineer is far more likely to look up a text-book to discover what is the practical method adopted than to discover the solution of some theoretical problem, and the ideal text-book should largely quote examples of practical methods and expedients. The chapter on mine surveying contributed by Mr. W. S. Hall is, however, an example of the brief discussion of the survey methods used for a special engineering purpose, and appears to be useful and clear.

There is a long appendix of some fifty pages on photo-topographic methods and instruments, being a paper by Mr. J. A. Flemer in the Report of the U.S. Coast and Geodetic Survey for 1897. Such a system has been much advocated in various quarters during the last few years, and it is interesting and ingenious. Under certain special conditions, such as those in the Canadian North-West, where the features are bold and open and where the field season is short, and where sometimes only occasional glimpses through the clouds can be had of the higher peaks, the method is efficient and economical. But under ordinary conditions it is neither, and as a method it cannot be said to be established, nor is it likely to be; and the inclusion of a detailed report on a tentative topographic method in a book devoted to large-scale engineering survey increases the size of the book, but not its value.

As regards the nomenclature of the book, we do not like the author's division of surveying into plane surveying and geodesy, although authorities can be found in favour of it. The term geodesy should be reserved for those scientific operations of which the object is the determination of the form and size of the earth. Some of the words used are new, *e.g.* "declinator," meaning the box containing the compass. The northings and southings of a traverse are here called "latitudes," and the eastings and westings "longitudes." We are glad to see that the author uses the word "plotting" and not "platting." The latter is sometimes found in American technical works and is objectionable in spite of its greater antiquity. C. F. CLOSE.

INSPECTION OF RAILWAY MATERIALS.

The Inspection of Railway Materials. By G. R. Bodmer, A.M.Inst.C.E. Pp. ix + 154. (London: Whittaker and Co., 1902.) Price 5*s*.

THE inspection of their products has long been a source of worry to the manufacturers of railway material, be it locomotives, bridges or rails. Consulting engineers have their own ideas as to what the tests should be; few specify alike, with the result that manufacturers have to make various qualities of material for the same purpose—a state of affairs not conducive to economy of manufacture.

The question of material is not the only trouble. Consulting engineers very often specify methods of manufacture for their material. Interference of this kind in works management is most expensive to the manufacturer; it upsets the sequence of the work, delays progress, and in the end has to be paid for by the railway shareholders.

A third complaint might be made by manufacturers, and one which very largely adds to the cost of work in many cases, and that is, what kind of man is the inspector? It is on this point the author of this book commences. He says:—

"The inspection of railway material is a class of work for which every inexperienced neophyte devoted to the engineering profession imagines himself to be qualified."

The author goes on to say that

"in reality, however, many qualifications are required to make a good inspector, and chief among these is experience, the one most likely to be wanting in a young engineer."

With this we thoroughly agree. In certain specifications the general clauses are such that the contractor is entirely in the inspector's hands, and if the inspector does not know his work the result is disastrous. Much has been written lately on the standardisation of locomotives, for instance, as a means of shortening the time of delivery; but given standard tests, non-interference in works practice and a practical man as resident inspector, there is no necessity to crystallise any design, for when all is said and done a thing of yesterday is old.

This book has evidently been written by one who has been through the "inspection mill." There is much evidence of this in the various chapters. Chapter ii. deals with rails, ordinary and tramway, fish plates, &c. We are told that in the case of fairly heavy rails it is possible to inspect four or five at a time. The reviewer could never do more than three continuously.

Steel sleepers are dealt with in chapter iii. The information is well up to date, although we cannot agree that the Indian sleeper fitted with punched up lugs cannot be gauged for gauge unless fitted with a length of rail, &c. The author might have explained that with this type of sleeper the position of the keys for normal gauge is outside the rail, for a medium curve one is moved inside, and for a very sharp curve both are placed inside.

On tyres and axles we find much useful information, and further on rolled material generally is very fully gone into, the tests being carefully explained. Chapter vii. deals very thoroughly with the condition governing the specifications for steel rails, more particularly discussing the mechanical tests, which vary very largely in present-day practice. The work concludes with a short account of the inspection of finished work dealing with various parts of rolling stock, and fulfils the intention of the author in being a brief guide to the inspection of railway material for the use of engineers. N. J. L.

OUR BOOK SHELF.

The Watkins Manual of (Photographic) Exposure and Development. By Alfred Watkins. Pp. 124. (Hereford: The Watkins Meter Co.; London: George Houghton and Son, 1902.) Price 1*s*. net.

THE author is universally known among photographers as the inventor of the Watkins exposure meters and as having devised methods of exposure and development whereby the results are rendered more certain than by the older "rule of thumb" procedure. In this manual Mr. Watkins has systematically set forth his methods of timing exposure and development, and as these methods are sound in principle and useful in practice, a complete and orderly presentation of them as is here given results in a handbook that must be of great value to all serious students of the subject. It is the most welcome photographic manual that we have received for a long time.

We should have much preferred it if the author had remained true to his title and not endeavoured to provide a book suitable for two distinct purposes, namely, as an exposition of the procedures that he has introduced and popularised, and also as a guide for the beginner. Anyone who will be instructed by the statements that the lens forms the image and that the plate receives the "lens image," that a box of plates must be opened only in the dark room, and so on, will be quite unable to appreciate the bulk of the volume. Moreover, the author's heart is evidently in those sections of the subject that he has made peculiarly his own. In these he is full and clear, and probably no one, however much he may have studied the matter before, will read these parts without learning a good deal. The other chapters appear to have been written unwillingly, for in them accuracy is sacrificed for the sake of an apparent simplicity, and the subjects they represent cannot be said to be treated of, they are little more than referred to. In learning to photograph, as in learning to speak, the natural method is first to learn to do what it is desired to do, and finally to learn the grammar or the theory. No one tackles a subject in the opposite direction except under the compulsion of a schoolmaster, and then generally he learns the subject badly.

In dealing with chemical and physical changes, one must have a mechanical conception of the process, and Mr. Watkins is generally happy in his illustrations. But when he represents the course of development as a simultaneous reduction to the metallic state of all the particles of silver salt made amenable to the action of the developer by the exposure, so that as the image gradually grows in density these particles are at one stage each one-quarter reduced, later one-half, while finally the whole of each particle is completely reduced, he selects an illustration that is not true to fact. But this is a mere detail. We heartily commend the book to those who know how to photograph and wish to increase their knowledge and improve their practice. C. J.

Nature Study and Life. By C. F. Hodge. Pp. xv + 514; illustrated. (Boston, U.S.A., and London: Ginn and Co., 1902.) Price 7*s*.

THE author of this little volume is convinced that the only true method of nature-study is by making children thoroughly acquainted with living animals and their ways, both in the wild state and in confinement. He will have nothing to do with technicalities as to their structure and classification, leaving these, if they are ever to be taught at all, for older pupils. The keeping of tame animals as pets, and the history of domesticated animals, so far as known, are regarded as important factors in the scheme. A similar mode of study is pursued in the case of plants, where the pupil is not bothered with a long string of technical names or wearied with details as to their structure. Their life and their relations to inanimate surroundings are the only things it is sought to teach. The author's mode of procedure is to induce the members of the class to write down the names of all the animals—both wild and domesticated—with which they are acquainted, to classify them roughly, and then to discuss some of the more important types at length.

That the author's method is not a mere empirical suggestion, which may or may not prove successful in the class-room and in the field, is evident from the introduction to the volume by Prof. Stanley Hall, of Worcester, Mass., who writes as follows:—"New as his method essentially is, it is now made public only after years of careful trial in the public school grades in Worcester, until its success and effective working in detail is well assured. Thus it has passed the stage of experiment, and is so matured and approved that, with slight local adjustments, it can be applied almost anywhere for children of from six or seven to thirteen or fourteen years of age."

In the United States the success of the method seems indeed to be assured, and there is accordingly every inducement to give it a fair trial in this country. The book is brightly and pleasantly written and well illustrated. Whether the author is altogether correct in the statement on p. 8, that the mammoth was a third taller and more than twice the weight of "our elephant," and that "the mastodon" was larger still, we may be permitted to doubt. We are also at a loss to know the particular kind of fossil deer indicated by the name *Cervus americanus*, a title properly belonging to the existing Virginian white-tailed deer. R. L.

Manual of Agricultural Chemistry. By Herbert Ingle. Pp. 412. (London: Scott, Greenwood and Co., 1902.) Price 7*s*. 6*d*. net.

AGRICULTURAL chemistry deals with a very extensive range of subjects, including the whole of the materials and operations with which agriculture is concerned. The plant, the soil and the animal are each of them subjects sufficient to satisfy a whole generation of workers; but agricultural chemistry includes all these and much more besides. No book ever has been written, and none probably ever will be, attempting to deal with the entire subject; the student must, therefore, fill his shelves with a great variety of books, by many writers, if he would have at command the information available on the subjects of agricultural chemistry.

The present manual represents the course of instruction in agricultural chemistry given at the Yorkshire College, Leeds. The course of instruction is a full one, and the matter has been carefully written out by the lecturer, Mr. H. Ingle. The book thus produced will be heartily welcomed by all students of agricultural chemistry; it brings together clearly and correctly a great mass of facts which can be found in no other single volume. Especial attention is given to questions connected with pure chemistry, organic and inorganic, and with physiological and analytical chemistry; less prominence is given to the problems of practical agriculture. Thus we have the percentage composition of crops, but not the composition of average crops per acre; the subject of rotations is also omitted Again, under animal chemistry, we have no discussion of the relation of food to animal maintenance, or to the production of work or animal increase. The values of foods for the production of heat are given, but the extent to which these potential values are utilised for animal requirements is not discussed. The epoch-making researches of Kellner and Zuntz on this subject are not referred to.

The author describes Grandeau's method for the determination of humus in soil, based on the solubility of this substance in alkalis. As a good deal of work is being done with this method both in America and in this

country, it may be worth while noting that it does not show the total humus, but only the humic acids. Berthelot has, in fact, shown that even boiling with potash leaves a considerable part of the organic carbon and nitrogen of a soil undissolved.

English agricultural writers employ two names for *Beta vulgaris*—"mangel" and "mangold"; Mr. Ingle employs the latter. The former spelling is, however, more correct. The word comes from the German description "Mangel-Wurzel," or scarcity root, alluding to its resistance to drought. The spelling has probably drifted into mangold from the golden colour common to the roots. R. W.

Ueber Aehnlichkeiten im Pflanzenreich. By F. Hildebrand. Pp. iv + 66. (Leipzig: W. Engelmann, 1902.) Price 1*s.* 9*d.* net.

PROF. HILDEBRAND, in his introductory remarks, takes exception to the use of the term "mimicry." He states that it is applied by zoologists when two very different animals show similar appearances which are of apparent benefit to one, and that the explanation of zoologists infers that these similarities are developed in the struggle for existence. The latter part of this statement is distinctly misleading, as it is doubtful if any zoologists regard such similarities as being developmental. The object of the book is to show that in the plant world mimicry rarely if ever occurs, and that similarities in plants or plant forms are mainly due to environment or ecological factors. The series of comparative sketches which Prof. Hildebrand has published form light reading, but they might with advantage have been worked up in greater detail.

Index to the Literature of the Spectroscope (1887–1900, *both inclusive*). By Alfred Tuckermann. Pp. 373. Continuation of the previous index by the same author published in 1888. (Published by the Smithsonian Institution, 1902.)

IN the previous index, extending from the dawn of spectroscopy (or even earlier, for references are made to papers published in the seventeenth century) to 1886, the author arranged the books and papers under 320 different sections, placed alphabetically. In each section the titles of the papers, the authors' names, and references to the original papers and abstracts are arranged in the alphabetical order of the authors' names. The present contribution is divided into two parts, part i. being an authors' index extending to 188 pages, in which the authors' names are placed alphabetically and the full title, year of publication and references to the papers and abstracts are given; and part ii. a subject-index beginning with history, books, spectroscopy in general, followed by nearly 300 divisions arranged alphabetically. In these divisions the authors' names are first given alphabetically, followed by the references to the papers with the year of publication, but without any reference to the titles or to contents of the papers which are not given in the titles. Thus under titanium there are five references; the first is in the *Wiener Anzeiger*, and does not appear in the author-index, the second is on ultra-violet spark spectra, the third on titanium as a comparison spectrum, the fourth on the arc spectrum, and the fifth on the shifting of the arc spectrum lines under the influence of pressure. The value of the index would have been enormously increased if the papers had been arranged alphabetically according to the subjects, and with the papers on the same subject placed in order of date instead of according to the authors' names. Such a system would have entailed more printing, but it would not have caused very much more work in preparation and would certainly have been worth the additional trouble.

The list appears to be very complete; it may be said to be more than complete, for some of the papers indexed do not deal with spectroscopy. Thus five papers on meteors which we have examined do not contain any reference to spectra, and one on the yellow variety of arsenic does not deal with spectroscopy; several papers are indexed which contain only micrometric measurements of the diameters of planets. It is perhaps ungracious to criticise in this manner a work which must have been very arduous to the author, but the inclusion of papers that do not refer to the use of the spectroscope may be the cause of much loss of time and trouble to workers, and this would not have happened if the subject-index had been prepared in the way above suggested.

Dr. Tuckermann must be congratulated on the conclusion of his work, which, notwithstanding the defects which we have mentioned, cannot fail to be of service to many investigators in this important branch of science. H. M.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Misuse of Coal.

NATURE of March 20, containing a most interesting communication by Prof. John Perry on the "Misuse of Coal," has reached me lately. Surely Prof. Perry takes an insular view of the matter. Like so many Englishmen, alas! he knows not the forest! The greater portion of the world cooks its food and makes itself comfortable on wood fuel, and though all the forests in the world would, according to European ideas, be inadequate to supply by their growth the present expenditure of coal (their fossilised remains), to overlook altogether the sun power which we can fix by growing wood fuel is surely, from even a European point of view, an oversight. Helmholtz compared the number of thermal units received by an acre of land in Germany during a year with the number of thermal units produced by burning the vegetable matter elaborated during a year. His calculation was that only the 1/1477th part of the sun's heat was thus rendered available.

On this basis it is possible roughly to calculate the maximum thermal efficiency as firewood of the wattle or Eucalyptus vegetation on the coast of Australia or South Africa. (Insolation is for the latitude somewhere about one-sixth greater at Cape Town than in mid-Germany; practically it is more on account of the clearer atmosphere.) The production of firewood is about five times as much; thus, taking Crottondorf as an example of a European forest giving one of the largest yields in timber, we have:—

Crottondorf spruce, mean yearly yield 143 cubic feet.
Quick-growing Eucalypts, S. Africa, do. 700 ,,

Or the maximum South African yield is five times the maximum European yield. But since the average weight of eucalypt wood is three times that of spruce, the heating power produced on an acre of Eucalypts must be set at about fifteen times that produced on an acre of northern and mid-European forest. Thus on the basis of Helmholtz's calculation a eucalypt plantation can, with the most favourable circumstances, in South Africa or on tropical mountains, store up, say, 15/1500 = 1 per cent. of the solar energy received on the unit of area.

The position in Cape Town to-day is that it is cheaper to plough the ground and plant a forest of quick-growing trees than to import coal from over the sea or by a long and expensive land journey. Firewood in Cape Town is worth nearly 1*s.* per cubic foot, and before the railway was extended to the diamond fields firewood there has fetched 1*d.* per lb., the price at which sugar has been retailed in England. No doubt from a British insular point of view coal at 2*l.* or 3*l.* per ton is a terrible misfortune. It certainly increases the cost of running machinery; but if this does not take place to a prohibitive extent, and if it makes the user of power careful not to waste it, it is not an unmixed evil. And if thereby afforesting is made a paying operation, it is at least open to discussion whether dear coal and good forests would not be better for England than an expenditure of 23,000,000*l.* sterling on

imported timber, and the evils, including physical degeneration of the race, and coal fogs in the big cities, which have been shown elsewhere to result from England's neglect of its forests. The reference to De Wet in Prof. Perry's communication is unfortunate: a small quick-moving army would probably have caught him. And surely cheap coal and luxury is not the *summum bonum*. Rather let us have hamlets of strong forest workers than the luxurious town dwellers of to-day with their decayed muscle and cheap mechanical power! Compare a European engine-driver with the runner castes of India and Japan. The engine-driver shows us perhaps fine inherited muscle, but going to decay for want of use; the Eastern runners show the development of muscle by both use and inheritance. Which would have the best chance of catching De Wet a hundred years hence?

As far back as 1882 the discovery was made by Sir D. Brandis and myself that Eucalypts planted on tropical mountains will produce wood fuel at the rate of 20 tons (dry weight at 60 lbs. per cubic foot) per acre per year in perpetuity. The eucalypt plantation reproduces itself when cut, without further expense, and its dry timber, heavier than coal (which, as met with commercially, weighs 50 lbs. to 52 lbs. the cubic foot) has an equal or a higher thermal power, bulk for bulk, than coal. We obtained this result as the maximum yield of *Eucalyptus globulus* on the Nilgiris, Southern India. No doubt there are other instances where higher yields are produced now, and no doubt also when the coal supply is exhausted, selection and experiment will produce a forest vegetation that will produce more than 20 tons per acre per year. The sugar beet and all the fruits and vegetables of civilisation show how the vegetable kingdom can be moulded to suit man's wants. If a chance tree on a chance mountain in a chance soil can produce the equivalent of 20 tons of coal per acre per year, it seems not unreasonable to suppose that by selection we can produce, say, double this, or 40 tons. To produce this in perpetuity we should probably have to find a tree with the moderate soil requirements of the Conifers. A powerful sun, a heavy rainfall, and a very rapid forced growth would be the essentials of such a production of wood fuel.

Looking at a rainfall map of the world, one sees that these conditions are fulfilled over about 8000 million acres of its surface (which is between one-fourth and one-fifth of the total land surface of 35,200 million acres). I take latitudes below 40° and rainfalls above 40 inches. One-half of this area under forest might thus yield the equivalent of 161,000 million tons of coal yearly. This is more than 288 times the world's present consumption of coal, assuming that coal and eucalypt timber are of approximately equal heating power. On the basis of the actual forest yields of to-day we have half this, or 80,500 million tons. In Germany, one-fourth of the total area is under forest, and this is held on the highest authority to be the suitable proportion for a thickly-peopled civilised country such as Germany. The forest should properly occupy a higher proportion in countries where large areas are pestilential and unsuited for human habitation. Putting this, however, aside, and taking the German standard of one-fourth forest, then on the basis of to-day's maximum yields we should obtain a yearly output of 40,250 million tons. And if to convert the maximum forest yield to an average forest yield we again divide by two, we obtain 20,175 million tons. Lower than this I do not think we can reasonably go for the class of forest under consideration. *It is a little more than thirty times the world's present consumption of coal.* The world's yearly output of coal recently was 663 million tons, says Prof. Perry.

Thus we see that the yield of firewood from the world's tropical and extra-tropical forests, whenever they are fully stocked and scientifically worked, will yield the equivalent of from thirty times to 122 times the present consumption of coal, or even up to 243 times the present consumption of coal if we succeed by cultivation in doubling present timber yield figures.

It may be objected that my figures are far in excess of those representing the yield of European forests and that they require confirmation. No doubt they are far in excess of European figures; but so also is the intensity of the vegetative process in these latitudes, and so also is the stature of the Sequoias of California, and the Eucalypts of Australia and South Africa above the stature of the biggest spruces and silver-firs of Europe. The Nilgiri figures I have quoted above were formally recorded in two official reports printed and published by the Madras Government in 1882.[1] They have since been confirmed by the measurements of forest officers who have subsequently had charge of the Nilgiri plantations. Similar figures have been obtained by myself and other forest officers in South Africa. They have been exceeded in several plantations in Natal, while at Johannesburg they have not been confined to Eucalypts, but have been obtained from *Acacia decurrens*, or black wattle, as well as from some other trees.

Therefore, "when our coal supply is exhausted, when all the races of the world have fought for the waterfalls and places of high tide," there will still remain that which Englishmen of all the civilised races of the world do most neglect—the forest.

D. E. HUTCHINS.

Grootvadersbosch, Swellendam, Cape Colony, May 14.

Cold Weather in South Africa.

WE have been getting exceptional weather here of late. General French was actually snowed up at Middelburg. A good general idea of the circumstances will be obtained from the telegrams abridged below from the *Diamond Fields Advertiser* of June 14.

Middelburg (Cape), June 11.—For the first time for sixteen years the town is covered to a great depth with snow. Kingwilliamstown, June 11.—A fierce thunderstorm occurred last night, accompanied by heavy rain. Port Elizabeth, June 11.—The train service between Graaff-Reinet and Rosmead is to-day stopped temporarily owing to heavy snowstorms—an unusual experience for South Africa. Cradock, June 12.—An exceptionally heavy fall of snow occurred in the Midlands on Tuesday night and yesterday. Queenstown, June 12.—The rainfall reported during the first five months of the year is the lowest recorded for the same period for the past thirty years. The drought has, however, been broken. Rain started on June 10, and during the night there was a heavy fall of snow. Kokstad, June 12.—There was a heavy snowstorm last night, accompanied by a heavy gale. The snow is several inches deep in the streets. Bloemfontein, June 12.—The weather is unprecedentedly cold. The hills round Thaba 'Nchu are covered with snow. Last night snow fell in Bloemfontein.

At Kimberley it has been intensely cold, with a low barometer, wind, rain and sleet, and afterwards heavy frost. With the one exception of July 12, 1886 (when Kimberley is said to have been under snow for the whole day), the maximum shade temperature registered is the lowest on record. For the eight days ending Sunday, June 15, the temperatures have been:—

	Observatory Screen.		Stevenson Screen.	
	Max.	Min.	Max.	Min.
June 8 ...	72°·0	34°·0	73°·7	33°·0
,, 9 ...	59°·0	39°·0	59°·8	38°·1
,, 10 ...	46°·2	38°·0	45°·9	37°·8
,, 11 ...	45°·4	36°·9	44°·9	36°·1
,, 12 ...	48°·3	31°·6	46°·8	31°·2
,, 13 ...	52°·1	25°·2	53°·7	24°·2
,, 14 ...	57°·0	26°·9	58°·0	26°·0
,, 15 ...	62°·0	29°·0	63°·2	28°·0

The maximum temperatures registered on June 10 and 11 are the lowest on record for any June. The maximum registered on July 12, 1886, was 35°·8. There was also a maximum temperature of 45° in July 1891. Both, however, were obtained under a Glaisher screen and are probably a little too low. Minimum temperatures lower than 25° have been registered perhaps three times; the lowest known is probably 20° in July 1888. All these previous instances have been quite transitory, the temperatures in each case being much higher both the day before and the day after. There seems to be no record of a cold spell having the duration of the one in question.

A SHORT PERIOD OF SOLAR AND METEOROLOGICAL CHANGES.[1]

IN continuation of the inquiries referred to in a former paper on Indian rainfall and solar activity,[2] attention has more recently been devoted to an examination of the variations of pressure over the Indian and other areas.

(1) It is well known that in India during the summer months (April to September) and during the winter months (October to March) low and high pressures respectively prevail. In the case of the latter, the pressure is found to exhibit very remarkable and definite variations, and is in excess every three and a half years on the average, while at these times of excess of high pressure the low pressure during the other six months of the year is deficient; so that every three and a half years or so the high pressure becomes higher and the low pressure is not so low as usual.

(2) Further, this short-period variation which appears in the mean variation of pressure over the whole of India is as well defined in the mean values for individual stations such as Bombay (Fig. 1, Curve F), Calcutta, Madras, Nagpur, &c.

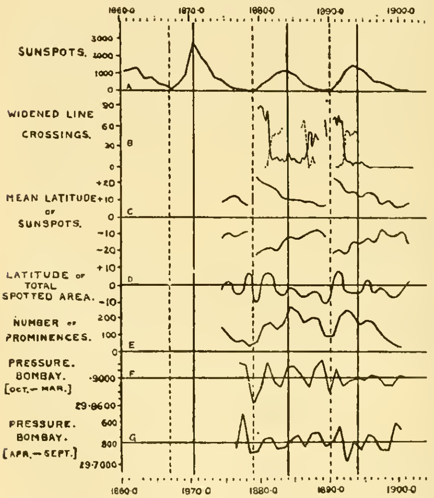

FIG. 1.

(3) The view that the variation of pressure in question over India and its neighbourhood is not due to local causes, but is produced by some external, or extra-terrestrial action, is considerably strengthened by an examination of the pressure curve of a very distant station such as Cordoba. Dealing with the pressures at Cordoba during the high-pressure six months, April to September, the curve (Fig. 2, Curves F and E) representing the variation from the mean from year to year is exactly the *inverse* of the curve representing the Bombay and other Indian pressures for the same months over the same period of time. The cause, therefore, which raises the mean value for the low-pressure months over the Indian area would appear to lower the mean value of high-pressure months at Cordoba simultaneously. In fact we have a see-saw.

(4) Further investigation shows that not only do the pressures of practically the whole Indian area exhibit variations from year to year which present very similar features, but that this is the case with other large areas.

Thus, for instance, it is found that the yearly mean pressures for Brussels, Bremen, Oxford, Valencia and Aberdeen (the only pressures that have been at present examined) are all remarkably similar in their variations from year to year; and it might almost be said that one curve representing the variations from the normal would approximately define the pressures at all these places.

The probable extra-terrestrial origin of these short-period variations led to a detailed examination of the records of the phenomena connected with solar spots and prominences, with a view of seeing whether similar variations, indicating changes in the solar activity, could be detected.

(5) A preliminary reduction of the Italian observations of prominences observed on the sun's limb since 1871 was first undertaken. The result of this inquiry indicates that, in addition to the main epochs of maximum and minimum of prominences which coincide in time with those of maximum and minimum of the total spotted area, there are prominent subsidiary maxima and minima having a similar short period, and also coinciding in time (Fig. 1, Curve E).

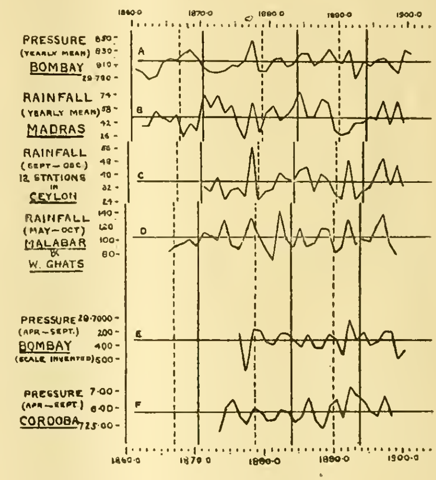

FIG. 2.

(6) Although these subsidiary prominence pulses are not distinctly duplicated in the curve representing the spotted area of the solar surface, it is to be noted that corresponding pulses are indicated in the curves which represent the change of latitude of spotted area from year to year; and in each case an increase in prominence activity is associated with a decrease of latitude of the spotted area (Fig. 1, Curves C and D).

(7) A comparison of these solar data with those already referred to relating to terrestrial pressures suggests that these simultaneous outbursts of prominences and changes of the latitudes in which the spots occur about

[1] "On Some Phenomena which Suggest a Short Period of Solar and Meteorological Changes," by Sir Norman Lockyer, K.C.B., F.R.S., and William J. S. Lockyer, M.A., Ph.D., F.R.A.S. (Read before the Royal Society, June 19.)

[2] "On Solar Changes of Temperature and Variations in Rainfall in the Region Surrounding the Indian Ocean" (*Roy. Soc. Proc.* vol. lxvii. p. 409).

every three and a half years are the true cause of the pressure changes; and that the varying intensity of solar activity within the sunspot period of eleven years produces an effect on the pressure and circulation of our atmosphere, thus affecting the whole globe meteorologically.

(8) The close correspondence between the epochs of these subsidiary pressure variations and those representing prominence frequency suggests, not only their very close relationship, but that the terrestrial pressure quickly answers to the solar changes, while so far as the work has gone it would appear that rainfall (Fig. 2, Curves A, B, C, D) and snowfall are subsequent effects.

(9) It may be remarked that we have already obtained evidence showing that this short-period variation is not the only one acting, but that the eleven-year and thirty-five-year periods apparently influence the short-period variations. But even this does not explain some anomalies already met with, and should the solar origin of these short-period pressure changes be subsequently confirmed, some of them not constant in all localities will have to be explained: and it is possible we may obtain in this way some new knowledge on the atmospheric circulation.

(10) The period of time included in this survey begins generally with the establishment of the full records of the Indian Meteorological Department in 1875 and extends to 1895, when the regularity of the widened-line phenomena was broken, as stated in a previous communication.

Addendum, dated June 26.

In continuing the above researches we have plotted the percentage frequency of the solar prominences derived from the Italian observations for each 10° of solar latitude N. and S. of the equator.

We find that the epochs of maximum prominence disturbance in the higher latitudes are widely different from those near the equator. The latter are closely associated with the epochs of maximum spotted area, the former occur both N. and S. at intervening times.

We have, then, two sets of strongly marked prominence outbursts occurring at intervals of between three and four years.

Both sets are represented closely in the Indian pressure curves.

Solar Physics Observatory.

THE FIRST MAGNETICIAN.[1]

"THIS booke is not for every rude and unconnynge man to see, but for clerkys and very gentylmen that understand gentylness and scyence."

This quotation from Caxton is prefixed by Prof. Thompson to his notes to the new edition of the "De Magnete."

Most students of electricity know that William Gilbert of Colchester is the father of the sciences of magnetism and electricity. They may have some idea of the extent of his discoveries and the general character of his work, but few who have not seen the celebrated book in which he recorded his results can have really grasped how much Gilbert knew and how thorough and complete were his investigations.

"He practised the experimental method of observation before Bacon wrote about it; his methods and discoveries excited the sneers of Bacon, the praises of Galileo and Kepler."

The book justifies the high claim put forward on its behalf by its latest editor, and the thanks of men of science are due to him and to all who have helped him for enabling them to learn what Gilbert did.

It was a happy thought to found the Gilbert Club, and the members of the club who have the chance of possessing this splendid volume, the outcome of many years of patient research and loving labour, are greatly to be envied.

The club was founded in 1889 to commemorate Gilbert's work and to issue a translation in English; at that date there was none, though one was published in America in 1893 The original edition was issued in 1600, and it was at first hoped that the translation might be ready in time for the tercentenary celebration at Colchester in 1900. This proved impossible, but the work is now complete and the result is admirable.

It will be of interest here to give a brief account of the work itself. Starting with the early history of the loadstone, its power of attracting iron known to the ancients and its property of setting in a definite direction discovered in the tenth or twelfth century, Gilbert in the first book of his treatise sets forth the various fundamental properties of a magnet and of magnetised iron, illustrating them by the experiments now familiar to all, and describing almost in every chapter some new discovery or some important law. He is continually appealing to experiment and accurate observation. "Deplorable is man's ignorance in natural science," he writes, "and modern philosophers like those who dream in darkness need to be aroused and taught the uses of things and how to deal with them, and to be induced to leave the learning sought at leisure from books alone and that is supported only by unrealities of arguments and by conjectures" But Gilbert lived too early; it was more than 200 years before the truth of his maxim was realised.

He was quick to appreciate at their true value the inaccurate observations of some who had gone before him. "Albertus Magnus writes," we are told, "that a loadstone had been found in his day which with one part drew to itself iron and repelled it with the other end; but Albertus observed the facts badly; for every loadstone attracts with one end iron that has been touched by a loadstone and drives it away with the other."

Among other things, we may note his observation that "a long piece of iron (even though not excited by a magnet) settles itself toward north and south"; but perhaps the greatest discovery in this book is contained in the last chapter, "That the globe of the earth is magnetick and a magnet," our "New and unheard of doctrine about the earth" he calls it. The doctrine is proved by the observations and experiments which are the subject of the rest of the treatise.

Book ii. deals with a number of examples of magnetic attraction, and in chapter ii., "On the magnetic coition, and first on the attraction of amber, or more truly on the attaching of bodies to amber," we find the beginnings of the theory of electricity. "For in other bodies," he writes, "a conspicuous force of attraction manifests itself otherwise than in loadstone; like as in amber, concerning which some things must first be said that it may appear what is that attaching of bodies and how it is different from and foreign to the magnetical actions, those mortals being still ignorant who think that inclination to be an attraction and compare it with the magnetic coitions," and so to illustrate electric actions he invents the straw electroscope. He divides bodies into "electricks," which are electrified by friction and attract light bodies, and "non-electricks," the metals and other conductors as we now call them. The effect of heat and moisture is studied and described, and the distinction between electrical and magnetic attraction fully made out.

With amber or other "electricks," "if indeed either a sheet of paper or a piece of linen be interposed there will be no movement. But a loadstone without friction

[1] "William Gilbert of Colchester, Physician of London, on the Magnet, Magnetic Bodies also, and on the Great Magnet the Earth." Pp. 246. Published in Latin, 1600. Translated and edited for the Gilbert Club, 1900, with notes by Prof. S. P. Thompson, F.R.S.

or heat whether dry or suffused with moisture invites magneticks, even with the most solid bodies interposed, even planks of wood or pretty thick slabs of stone or sheets of metal. A loadstone appeals to magneticks only, towards electricks all things move."

He has no mercy on those who would make a perpetual-motion machine by means of the attraction of a loadstone.

"But they have been little practised in magnetick experiments who forge such things as that. . . . Oh that the gods would at length bring to a miserable end such fictitious, crazy, deformed labours with which the minds of the studious are blinded."

Book iii. is on Direction, the property of the magnet to point north and south. At the outset Gilbert recognises that the compass needle deviates from the true North Pole by an amount which varies at different points on the earth. "But it must be understood," he says, "on the threshold of the argument (before we proceed further) that these pointings of the loadstone or of iron are not perpetually made toward the true poles of the world, do not always seek those fixed and definite points or remain on the line of the true meridian, but usually diverge some distance to the east or west."

The fundamental laws of the magnetisation of iron by contact with another magnet by induction either from a loadstone or in the earth's field are clearly set out. Gilbert knew, too, how to demagnetise a magnet. "Putting the whole iron in the fire," he writes, "blow the fire with the bellows so that it may be all aglow and let it remain a little longer time red hot. When cooled (so, however, that while it is cooling it does not rest in one position) . . . you will see that it has lost the verticity it had acquired from the stone." Verticity is the name given to the property of pointing north and south.

Book iv. deals with "Variation," the angle between the true and magnetic meridian at any point, and though we cannot agree with Gilbert that "the variation is caused by the inequality of the projecting parts of the earth," or that "the variation in any one place is constant," we can admire his skill and resource in utilising the scanty material at his disposal and in devising methods to measure the amount of the variation.

In Book v. the action of a dipping needle is described and explained, while Book vi. treats of the "Globe of the Earth the Great Magnet."

Any notice of this edition of the "De Magnete" would be incomplete without some reference to the notes contributed by the editor.

During the work of revising and editing the English translation of "De Magnete," many points, as Prof. Thompson writes, came up for discussion requiring critical consideration and the examination of the writings of contemporary or earlier authorities. The results of some portion of this labour have been collected in the form of notes. The text has with great judgment been printed just as Gilbert left it; in fact, comparison shows that throughout the English and the original Latin versions run page for page. The notes cover some seventy pages, and are replete with curious and interesting information. Take, for example, that relating to the picture of the blacksmith striking the iron while it lies north and south, given on p. 139, which we have reproduced. It appears that woodcuts containing human figures are rare in the art of the sixteenth century, and Prof. Thompson traces Gilbert's picture to a book of fables by Cornelius van Kiel, published at Cologne in 1594,

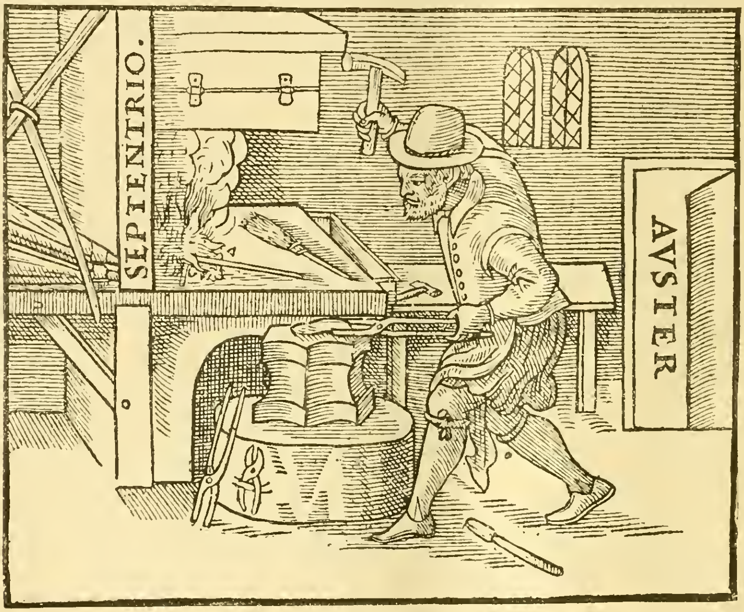

FIG. 1.—The Blacksmith making a Magnet.

where it is used to illustrate a fable of the blacksmith and his dog. The dog has been omitted in the Gilbert picture, the words Septentrio and Auster have been added and some other details modified, but there is no doubt where the picture came from.

Another note of interest is that to p. 165, dealing with the discovery of the mariner's compass, its construction, and the wind-rose or chart of the winds marked on the card of the compass. The earliest known examples of the wind-rose are on certain Venetian charts dating back to 1426 or 1436. Not less interesting is the paper which some five years since Prof. Thompson read before the Bibliographical Society on "Peter Short, Printer, and his Marks." This, however, is not in this volume. Peter Short, the hitherto unknown printer of the book, used as his mark the device of a serpent entwined round a T-shaped support, and the investigation as to why this mark was used has led to an interesting chapter in the history of the printers of the sixteenth century.

But enough has probably been said to convince even an unwilling reader of the value of the book "De Magnete" and of the services which the editor and his colleagues have rendered to science by the issue of this English edition. They are to be congratulated on the results of their labour of love, which, though it has cost them many hours of toil, has had so successful an issue.

R. T. G.

RECENT HISTORY OF THE ROYAL SOCIETY.[1]

WHEN the "Record of the Royal Society" was first issued in 1897, further editions of that interesting compilation were promised, and the Society has considered the opening of the new century an appropriate time for fulfilling that promise. Although there is not much of especial importance in the history of the Society to chronicle during the four years which have elapsed since the issue of the first edition, no one will quarrel with the Council for having taken this opportunity of issuing a work which contains additions of so much interest as does the "Record" before us.

The first edition was noticed in our columns in 1897 (see vol. lvi. p. 343), and the present volume gives us, with but slight modification, the historical material contained in the first edition. The work, however, has extended from a manual of 224 pages to a substantial volume of 427 pages, and this increase in bulk is almost entirely due to the valuable list of the Fellows of the Society elected since its foundation, arranged in chronological order of election, with an alphabetical index.

While the main portion of the contents of the first edition remains unchanged, the short period which has elapsed between the two issues of the "Record" has seen modifications in some old associations of the Society. The Botanic Gardens, Chelsea, formerly known as "The Physick Garden," established in 1721, after enduring various encroachments upon its boundaries and sundry risks of absorption into the maw of the London builder, has found salvation in that essentially modern sanctuary for neglected charities, a scheme of the Charity Commissioners. This garden was granted by Sir Hans Sloane to the Society of Apothecaries in February, 1721, on conditions mentioned in the notice in NATURE already mentioned. In the event of the Society of Apothecaries at any time failing to fulfil these conditions, or converting the garden into buildings for habitations or any other uses save as a physic garden, the premises were to be held in trust for the Royal Society, by which it was to be held under like conditions, the obligations in this case being to the Royal College of Physicians. The Society of Apothecaries appears to have carried out the prescribed terms, but in 1861 evinced a desire to be relieved of its charge, which, however, the Royal Society showed no anxiety to assume, and the garden, suffering in the meantime some curtailment on the building of the Chelsea Embankment, remained under its original tenure until 1898, when the Society of Apothecaries, anxious to be rid of the burden of its maintenance, applied to the Charity Commissioners to draw up a scheme for the administration of the garden. Under this scheme, which was drawn up in consultation with the Council of the Royal Society, the management of the garden is placed in the hands of the trustees of the London Parochial Charities, with a committee of management of seventeen, upon which each of the bodies named in Sir Hans Sloane's original deed, viz. the Society of Apothecaries, the Royal Society and the Royal College of Physicians, has one representative; there are also representatives of certain educational authorities, and nine nominees of the trustees above mentioned. The committee is to provide for the maintenance of botanical specimens of living plants for teaching purposes and for the supply of botanical specimens for external instruction, and may also provide instruction, by means of lectures or otherwise, in botany with especial reference to the requirements of elementary education.

Another and more familiar name has disappeared from the list of institutions carried on under the ægis of the Royal Society. The Kew Observatory, built by King George III. on the site of an old monastery in 1769, for observing the transit of Venus which occurred in that year, was handed over by the Government in 1842 to the British Association, who maintained it until 1871. In that year Mr. J. P. Gassiot, F.R.S., executed a deed of trust for the endowment of the Observatory with a sum of 10,000*l*., the income to be administered by a committee of the Royal Society for the purposes of the Observatory. Such a committee was duly appointed, and assumed control of the Observatory, being subsequently incorporated under the title of the Kew Observatory Committee.

Under the scheme for the establishment of the National Physical Laboratory, the Kew Observatory Committee has been wound up, and the Observatory has become incorporated in the larger institution, of which it forms a department. The conditions of Mr. Gassiot's endowment are, however, observed by the retention, as a body independent of the governing body of the Laboratory, of the Gassiot Committee of the Royal Society, composed of those Fellows of the Society who are members for the time being of the executive committee of the Laboratory.

So much has been written lately in these columns and elsewhere about the National Physical Laboratory that there is no occasion to enlarge upon this subject further than to say that its scheme of management and organisation is set out in full in the volume before us, which also contains the full text of the Gassiot declaration of trust.

Another interesting document published in the "Record" is the royal warrant for the board of visitors of the Royal Observatory, Greenwich, granted by His Gracious Majesty the King on May 23, 1901.

The list of benefactions is extended by the addition of two bequests received since 1897—the bequest of Sir William Mackinnon, who left to the Society the residue of his estate, upon trust, for the foundation and endowment of prizes or scholarships for the special purpose of furthering natural and physical science and of furthering original research and investigation in pathology. The first award under this bequest was made last year to Mr. J. J. R. Macleod, M.B., for researches in pathological chemistry. The other bequest is one made by the late Prof. David Edward Hughes, the income "to be annually awarded either in money or in the form of a

[1] "The Record of the Royal Society of London." Second edition, 1901. Pp. vi + 427. "Year-Book of the Royal Society of London, 1902." Pp. 265. (London: Harrison and Sons.)

medal, or partly one and partly the other, for the reward of original discovery in the physical sciences, particularly electricity and magnetism, or their applications." A gold medal, to be called the "Hughes" medal, will be awarded for the first time this year.

These bequests involve corresponding obligations, as may be seen under the heading of "The Trusts of the Royal Society," and the multiplicity and variety of these and similar responsibilities, duly recorded in the volume under review, appear to have stimulated the Council to something in the nature of a protest and an appeal; for, by a memorandum facing the first page of the "Record," we learn that the Council has arrived at the conclusion that it is neither to the advantage of the Society nor in the interests of the advancement of natural knowledge that the already long list of medals should be added to, and the Council expresses the opinion that no further bequests for awards as prizes for past achievements should be accepted by the Society. The memorandum then proceeds to direct attention to the fact that the funds belonging absolutely to the Society and available without restrictions for its general purposes are very few indeed, and that the usefulness of the Society has been greatly hampered by the lack of such funds.

These facts are familiar to those acquainted with the working of the Society, but outside this circle there seems to exist a general impression, whether it be due to the Royal Society's ancient and honourable association with the throne, or to its occupying handsome premises in Burlington House, or to its entertainments in the London season, that it is a wealthy body, able to dispense material assistance to all and sundry undertakings in the wide field of natural knowledge. How far this is from the truth may be seen from the statement of the Society's income published in the "Year-Book." In this we see that the total regular income of the Society, apart from funds which it administers in a fiduciary character, amounts only to about 5000*l*., and out of this, supplemented by various small miscellaneous, and vicarious, receipts and a portion of the Government publication grant, provision has to be found for an expenditure which last year amounted to 2572*l*. on its publications alone, and 1300*l*. for its "Catalogue of Scientific Papers," in addition to all the expenses of establishment and library. Such a condition of affairs, hampering, as we are told it does, the usefulness of the Society, which has been aptly described by a distinguished foreign savant as "the mother of learned societies," and renders almost daily to the nation important services in matters of deep concern to the people in all parts of the Empire, is testimony only too eloquent to the indifference with which the pursuit of science is regarded in this country.

Space forbids us to refer at length to other undertakings in which advance is recorded in this volume. One of the most important is the completion of the "Supplementary Volume of the Catalogue of Scientific Papers," a volume of 807 quarto pages containing a list of the papers not previously catalogued in the volumes already published, for the period ending with 1883. The Society has already embarked upon the compilation of a similar catalogue for the period 1883–1900. With the completion of this work, however, the Royal Society's direct responsibilities in this matter will cease, the task being taken up from that point by the organisation, to which attention has more than once been called in these columns, of the "International Catalogue of Scientific Literature."

Other matters of more strictly domestic interest are duly recorded. The Society's collection of portraits and medals has received some notable additions. The lists of presidents and other officers, and of the recipients of the Society's medals, are brought up to date.

But perhaps the most interesting part of the volume is the list of Fellows of the Society from its foundation up to the present time. Such a roll of worthies furnishes a wealth of suggestion to the student of natural knowledge, and their biographies, if they could be presented to us in due sequence, would form an epitome of the history of scientific advance during the past 240 years which might almost be said to be synonymous with the history of the development of modern England. A word must be added in praise of the interesting series of portraits which is begun in the "Record," reproduced from photographs made by Sir William Abney from pictures in the possession of the Society. The present volume contains portraits of Sir Isaac Newton, Henry Oldenburg, Lord John Somers and Sir James Burrow, and we are promised a continuation of the series in future editions of the work.

The principal new feature in this year's "Year-Book," now in its sixth issue, is the incorporation of the complete official list of Fellows of the Society living on January 1, 1902, in place of the abbreviated list which has hitherto done duty in this work. This expanded list has added twenty pages to the size of the handbook, which contains besides, among other current information, the statutes and standing orders of the Society, lists of its Council and its twenty-six standing committees, the regulations for the administration of the Government grant for scientific investigations, the president's anniversary address and the annual report of the Council, with a statement of accounts and obituary notices of Fellows deceased. Appended to the Council's report is the report of a committee of the Society upon the vexed question of the organisation of philosophico-historical studies, a subject which has been already much discussed in the Press. Altogether the "Year-Book" indicates clearly enough how multifarious and important are the activities of the Royal Society.

THE FUTURE OF THE VICTORIA UNIVERSITY.

DURING the next few months the Privy Council will be called upon to come to a decision on a matter vitally affecting higher education in the north of England. The Victoria University, which has been in existence for twenty-three years, has come to a stage in its career when its future must be definitely settled. Liverpool has applied for a separate charter, and Owens College gives its hearty support to the establishment of three distinct and independent universities in place of the present federation.

The ambition of Manchester to have an independent university is not of recent growth. In the year 1641 a petition was presented to Parliament asking for a charter, but rival claims were brought forward by the town of York and nothing came of the effort. A fresh start in the same direction was made in 1836, but only resulted in the affiliation of the Manchester Academy to the London University. The more recent attempts of Owens College to establish a university in the city of Manchester will be in the recollection of many readers of NATURE. The opposition of Yorkshire (history repeats itself) was again successful, and led to the foundation of the Victoria University, which has, on the whole, worked well. What, then, are the reasons for its proposed dissolution?

The functions of a university are threefold—to teach, to advance knowledge and to examine. The more intimately these three functions are interwoven, the more effectively will the university fulfil its purpose. Their separation has been the great impediment to the progress of university education in this country. This is beginning to be recognised, and the recent efforts of Wales, of Birmingham and of London all tend in the direction of subordinating examination to teaching and of giving a proper place in the university ideal to research and advance of knowledge.

The Victoria University was founded in order to establish a greater harmony between teaching and examining

than was possible under the old system, which gave the London University control of the examinations. This worked well for a time, but owing to the growth in the number of students, owing also to the different directions in which the three colleges are developing, we are rapidly drifting back to the old state. Victoria University is now practically an examining body, which unites all disadvantages, for while on the one hand it controls the teaching too much in some directions, it is unable to secure uniformity of standard in others. This is a fundamental defect of the federal system, which can only work well during the early growth of the federated colleges, and will always break down as soon as some of the colleges are strong enough to stand alone.

As a mere piece of administrative machinery, the federal university must always be clumsy and wasteful. Its statutes and regulations must be framed to satisfy the various and sometimes diverging requirements of the different colleges. This can only be done by means of endless meetings and constant compromises. It is the duty of every teacher to give up a portion of his time to administrative work, and he will be glad to do so if satisfactory results may be arrived at without a wasteful expenditure. Every man has only a certain amount of strength and energy, and every hour spent in the committee room is so much taken away from his power of promoting knowledge. Simplicity of machinery is a matter of primary importance in university organisation, and it is not too much to assert that whatever success the Victoria University has achieved, it has done at the expense of taking away a very substantial and unnecessary amount of time, which its teachers might more profitably have spent in their studies or laboratories.

The objections to the splitting of the Victoria University are chiefly based on the assumption that a multiplication of universities is bad in itself. "Union is strength" is a good party cry, but the saying is not true when the union is of the kind one gets in a three-legged race. If there are universities in Manchester, Liverpool and Leeds, it is further asked, why not one in Sheffield or in Oldham, Rochdale or Burnley? Such objections are not serious, and savour too much of the political platform. We might as well argue that we should not eat and drink enough because we might possibly eat and drink too much. Surely, if a town possesses a college of sufficient standing to supply the highest teaching in its various faculties, if it is established on such financial basis as will secure its permanence and its capability of attracting teachers of eminence in the future, and if there is a sufficient supply of students, no reason can be urged against the creation of a fresh university.

Competition and rivalry, it is argued, will lower the standard of a degree. This objection springs from that distrust of the teaching profession which has been one of the chief causes of the backward state of education in this country, and is only now being slowly overcome. Because it is believed that a teacher, if left to himself, will neglect his duties, all kinds of safeguards, external examinations and inspections are invented, which may be excellent if intended to help the teacher, but are bound to break down if used to overlook and correct him. The three Dutch universities of Amsterdam, Leyden and Utrecht are nearer to each other than Liverpool, Leeds and Manchester. Though subject to certain State regulations as regards curricula, the teachers are entirely free to fix their own standard of examination. Any of these universities could, if it wished, lower its standards and give its degrees on easier terms than the other two. If they do not do so, it is because they are not foolish enough to commit suicide, but desire to attract the best students, and keep them for post-graduate and research work. Rivalry will be found to act as a healthy stimulant and not as a temptation.

America is sometimes pointedly referred to as an example of the evil effects of the multiplication of universities, and of the danger which accompanies the complete freedom of power to confer degrees. This freedom has apparently led to the depreciation of degrees in the case of a few institutions which abuse their privilege. But the standard of university education in a country should be judged by its highest and not by its lowest work, and when we think of university education in America we think of Harvard, of Yale, of Cornell and other places of high reputation, and do not trouble about a few insignificant places, which after all do very little harm.

If we could secure another half-dozen efficient and progressive universities in England, they would not be too dearly purchased, even if by some mischance one or two were established which did not justify their existence. But there is no fear as regards the immediate question at issue that any lowering of standard will result from the separation of the three northern colleges. In this country it is the old and not the new universities which are tempted to give degrees on insufficient attainments, and can do so without loss of prestige.

There are, of course, matters in which cooperation is desirable. Different entrance or preliminary examinations would obviously be objectionable and complicate the work of the schoolmaster who prepares boys for the university. Unification is here called for, not only as between the three colleges of the Victoria University, but throughout the country. The question of separation should not be mixed up with the no doubt very important question of admission to a university course.

A plausible argument against the multiplication of degree-giving bodies is found in the case of medicine, where the degree carries a qualification with it. The fact that this objection has been very strongly urged shows that our present system is not understood, and that separation is called for in the interest of a clearer definition of the meaning of our degrees. Efficiency is most easily secured if the burden of responsibility is placed on the right shoulders. Let each college give its own stamp to its own graduates, and the college will take better care to secure good teaching than while it can shelter itself behind the nondescript "Victoria University." This holds with special force where the examination, as in medical subjects, is to a great extent of a practical character. It is impossible in these cases to secure equality, and if the public is induced to think that the training or even the examination test is necessarily identical the public is deceived. If separation means the clearer realisation of the nature of the training received, separation is an advantage.

It will be to the ultimate good of each institution, if it feels the weight of its responsibility, and is more immediately made to suffer in public estimation for deficiencies in any of its departments. The effect of this feeling of responsibility is very real and swift. Liverpool has already raised a large sum of money conditionally on a charter being granted, and Leeds has put down its wants at a high figure. What is all this money wanted for except to make the teaching more efficient? It is wanted just as much whether the Victoria University remains as it is or divides; but the probable establishment of separate universities has roused the feeling of responsibility, and brought the gaps and deficiencies home to the governing bodies and to the public.

One further and very cogent argument must be brought forward. University education is often looked upon too much as a matter standing by itself, and without relationship to the previous training of the boys at school, or the parallel training in technical colleges. If a coordination of education is desirable, a federal university of colleges situated in three large cities becomes an impossibility. It is not necessary to argue this point in detail. Those who know the conditions of educational facilities in the north of England, will realise that the great diversity

which exists in the three towns is bound to render one common organisation so cumbersome that it would necessarily check the freedom of development which is essential to success. Speaking for Manchester alone, does it need further argument that a more effective university may be formed by a close cooperation between Owens College, the Municipal School of Technology, the School of Art, the College of Music, and the various theological colleges, than is possible with the present federation, which is confined to Owens College alone? And is it not obvious that the interest in higher education which would be roused by the common feeling of the governing bodies of all these institutions for a great university in Manchester will more effectively secure a high standard of work and a progressive spirit, than the artificial union of three colleges in different towns? In our effort to secure educational freedom we count on the sympathy of all who are truly anxious for educational progress, and we count more especially on the help of those who are now working out a similar problem in the University of London.

ARTHUR SCHUSTER.

NOTES.

WE regret to see the announcement of the death of M. H. Faye, the eminent French astronomer, at the age of eighty-eight years.

DR. J. G. GARSON has been appointed assistant general secretary of the British Association, in succession to the late Mr. G. Griffith.

SPECIMENS of volcanic dust collected in St. Vincent and Martinique, during the recent eruptions, which have been placed by the Colonial Office at the disposal of the Board of Education, are exhibited in the Western Galleries of the Victoria and Albert Museum. To this exhibit there has been added some dust which fell in Barbados, with chemical analyses of the same, and drawings of the minerals which it contains.

THE United States Congress has amended the law which provided for the opening of the Universal Exposition at St. Louis, May 1, 1903, by deferring it for one year. This has been done for many reasons, the principal being that, since its inception, the scope of the exhibition has enlarged. Up to the middle of June the money available for the exhibition, including State and national appropriations, amounted to more than 4,000,000*l*.

A CORRESPONDENT sends us a cutting from the *Manchester Guardian*, announcing that Mr. Assheton Smith has consented to present to the University College of North Wales a site on the Menai Straits for the erection of a marine zoological station. A special fund for the erection of this station is being started, and already Mr. H. R. Davies, of Treborth, who has acted as treasurer of the Puffin Island station since 1892, has led off with a handsome subscription.

WITH respect to the recent coloured sunsets that have been and are being seen in this country, it is interesting to note that similar phenomena are being observed in Germany. Thus the Berlin correspondent of the *Standard* writes (July 7):—"For some time past, both at sunrise and towards dusk, there has been visible here a remarkable glow of colour on the horizon, the sky exhibiting an appearance of unusual beauty. Men of science put forth the theory that this phenomenon is caused by particles in the air emanating from the fiery mass ejected by Mont Pelée." The coloured sunsets referred to last week (pp. 222, 230) were noticed at Lewisham on the evening of June 26. Mr. R. McLachlan, F.R.S., writes to say that when facing nearly due east his attention was attracted by a peculiar tint in the sky. On proceeding to the front of the house the effect was extremely brilliant, the red predominating. Mr. McLachlan thinks the tint in the eastern sky was probably due to reflection. Mr. A. R. Tankard writes to confirm the observations of remarkable sunsets at Madeira, described by Mr. F. W. T. Krohn in NATURE of June 26. He says that the peculiar sunset effects were not visible in the district of the Canary Isles and Madeira during April. As the chief eruptions in Martinique and St. Vincent took place in the first two weeks of May, and the curious effects described made their appearance subsequently, namely, in the early days of June, their connection with the eruptions is rendered probable.

A NOTE in a recent number of the *British Journal of Photography* (July 4) gives a brief account of a balloon voyage of a very uncomfortable nature that was made by Dr. Miethe in company with Lieutenant Hildebrandt. The account, which is taken from the *Photographisches Wochenblatt*, states that the ascent was made at Tegel in the afternoon at three o'clock, and the balloon came to earth at half-past six between Nieder-Finow and Liepe. At the ascent the balloon passed first through a mist, and then suddenly into a thunder cloud. After attaining a height of 200 metres, the balloon was suddenly carried to an altitude of 2000 metres, and then as suddenly fell half that distance. Meanwhile the storm was proceeding, but although the travellers did not see the lightning they were deafened with the thunder, and pelted with rain, hail and sleet. In their rapid leaps and plunges the car was frequently on a level with the balloon, and the tow-rope above their heads. The violent rocking of the car also added to the danger. Watches were not thought of, but according to the barograph this frightful experience must have lasted half-an-hour, when, through loss of gas by pressure, the balloon fell from a height of 2200 metres upon a dense wood of beeches, but for which the travellers would probably have lost their lives. One of them descended by the rope, and obtained help from the villagers at Liepe.

WE have to record the death by drowning, on Tuesday, July 1, of Mr. A. D. Hogg, a student of the Royal College of Science, London. Mr. Hogg, who had been a botanical assistant to Prof. Bayley Balfour in the University of Edinburgh, his native place, came to London and the Royal College of Science as a National Scholar in the autumn of 1901. Having obtained high qualification in botany, zoology and geology, he recently proceeded to St. Andrew's, at the suggestion of Prof. Howes, to study under Prof. McIntosh, in preparation for his return to South Kensington and zoology in the coming autumn. On the evening of his first day in the Gatty Marine Laboratory, seeking quietude and respite from the western sands, which were crowded at the time, he wandered to the mouth of the river to bathe. Not knowing the dangers of the spot, he swam out and was overcome, and in his loss science has become the poorer by an earnest and promising student.

REPORTS from Vienna, published in the *Daily Mail*, state that a severe earthquake lasting twenty seconds occurred at Salonica at 4.20 p.m. on Saturday, July 5. Before the news reached Vienna the instruments at the Laibach Seismological Observatory registered a great disturbance towards the south-east at an estimated distance of 600 miles. Later telegrams state that the earthquake was felt right across the Balkan peninsula. The shocks began on Saturday afternoon, and continued with frequent intervals until midday on Monday. A very cold wind is said to have accompanied the earthquake. More than 200 houses were wrecked at the village of Bani, three miles from Salonica.

IT is reported that two slight shocks of earthquake occurred in the neighbourhood of Cheadle, Cheshire, on July 8.

WE regret to learn of the death of the Abbé Maze, on June 17, at the age of sixty-six years. He had been for many years one of the editors of our contemporary, *Cosmos*; his first connection with that journal was as meteorologist after the Franco-Prussian War of 1870-1, and he was for some time secretary of the French Meteorological Society. About twenty years ago he undertook a laborious investigation into the periodicity of rainfall, which he has left uncompleted; it is said that he had established a double period of 6, and 6×7, or 42 years, for the recurrence of similar general phenomena. He was also engaged for many years on a history of the thermometer, and has left in manuscript a large amount of valuable information upon this subject, collected from every available source, and which we hope will eventually be brought to light.

THE *Morning*, the auxiliary ship of the National Antarctic Expedition, sailed yesterday for Lyttelton, New Zealand, *en route* to the Antarctic regions, where it is intended to meet the *Discovery* with supplies, and to render any other services which may be required. From an article in the *Times* we learn that while the main object of the *Morning* is to act as tender to the *Discovery*, still she is well equipped with scientific instruments of various kinds, some of which have been supplied by the Admiralty, including survey instruments, a large photographic equipment, sounding gear, and apparatus for collecting at least the surface fauna of the ocean. Constant meteorological observations will be taken, and in other respects as far as possible the staff on board the *Morning* will do its best to supplement the work of the *Discovery*. The captain of the *Morning* and commander of the relief expedition is Mr. William Colbeck, who was one of the staff of the *Southern Cross* Antarctic Expedition, on which he took the observations and drew the charts.

ACCORDING to a recent paragraph in the *Times*, the arrangements for the Scottish National Antarctic Expedition, under the leadership of Mr. W. S. Bruce, are making satisfactory progress. The Norwegian whaler *Hekla*, which Mr. Bruce recently purchased for the expedition, is to be renamed the *Scotia*. The ship is now being reconstructed on the Clyde, at Troon, by the Ailsa Shipbuilding Company, under the guidance of Mr. G. L. Watson, the well-known yacht designer. The *Scotia* is a barque-rigged auxiliary screw steamer of about 400 tons register. New deckhouses are being built, a larger one aft and a smaller one forward divided into a laboratory and cook's galley. A second laboratory and dark room is to be fitted between decks. The ship is being specially fitted to carry on oceanographical research, both physical and biological. Two drums, each containing 6000 fathoms of cable, for trawling in the deepest parts of the Southern and Antarctic Oceans, are being taken. Mr. Bruce intends to follow the track of Weddell and to explore the Ross deep, working eastwards from the Falkland Islands.

A NUMBER of papers dealing with various aspects of the recent eruptions in the West Indies appear in the current issues of the geographical and other scientific journals. A short article on "Martinique und sein Vulkanismus," in the June number of *Petermann's Mitteilungen*, by Dr. Emil Deckert, is accompanied by an excellent map of the island. Dr. Michel-Levy, director of the geological survey of France, contributes a paper on the Mont Pelée eruptions, with some admirable geomorphological diagrams, to the *Revue générale des Sciences*. In the *Geographical Journal* for July Mr. E. André describes a visit to St. Vincent, and some excellent photographs are reproduced, while Mr. H. N. Dickson gives a narrative of events, advancing the view that the destruction of St. Pierre was caused by a tornado originating in the hot gases issuing from the crater of Mont Pelée. A paper on the Windward Isles, by Dr. J. W. Spencer, appears opportunely in the *Transactions* of the Canadian Institute; it is illustrated by a number of plates and six valuable charts showing the contour of the sea-bottom.

THE fate of M. Andrée is still a subject of speculation. A Reuter telegram from Winnipeg states that the Rev. Mr. Fairies, an Anglican missionary among the Eskimos within the Arctic Circle, has arrived there and repeats the story, which was brought two years ago by an Eskimo to Port Churchill, that a band of natives found M. Andrée and party 300 miles to the north of Port Churchill. On approaching them M. Andrée fired a gun. The natives interpreted this as a hostile act and set upon the explorers and killed them. The Hudson Bay Company offered a large reward to the messenger to bring some relic. He departed, but never returned. Mr. Fairies described an instrument resembling a telescope, which was taken from the outfit and carried with other loot to the Arctic Circle by the Eskimos.

THE seventeenth annual meeting of the Photographic Convention of Great Britain was opened at Cambridge on Monday, when Sir Robert Ball, the new president, delivered an address on astronomical photography.

THE Brazilian Minister and the staff of the Brazilian Legation will attend the meeting of the Aëronautical Society to be held on Thursday next, July 17. The following papers will be read:—"The 'Peace' Balloon of the late Senhor Augusto Severo," by Dr. Carlos Sampaio and Mr. Eric Stuart Bruce; "Balloon Ascents in Thunderstorms," by the Rev. J. M. Bacon; "A Performance of the Bristol War Balloon during the South African War," by Captain H. B. Jones, R.E.; and "The Cycala Flying Machine," by Dr. Charles Zimmerman.

THE Sydney correspondent of the *Daily Mail* reports that the drought has become intensified in Queensland and in parts of New South Wales, while there has been rain elsewhere. The New South Wales rainfall for June on the coast to the south of Sydney is 95 per cent. below the average of the corresponding month in past years. In the immediate neighbourhood of Sydney the deficiency is 91 per cent., on the Hunter River 85 per cent., on the North Coast 93 per cent., on the Darling River 84 per cent., and between the Darling, the Lachlan and the Bogan Rivers 87 per cent.

A FEW examples of the practical application of scientific education in Germany are given in the *Journal* of the Society of Arts. The sugar industry is the first illustration of the progress of industry through science. In 1840, 154,000 tons of beetroot were crushed, from which 8000 tons of raw sugar were produced, showing about $5\frac{1}{2}$ per cent. of raw sugar extracted from the root. Twenty years later, 1,500,000 tons were treated, which produced 128,000 tons of sugar, or about 8 per cent. Last year about 12,000,000 tons were crushed, which produced 1,500,000 tons of raw sugar, raising the percentage to 13. This advance is due entirely to scientific treatment. The production of dry colours, chemicals and dyes in Germany shows a corresponding increase in production and dividend-paying capacity. The great increase of earning capacity is due largely to the constant labour of trained men, who by application of their technical knowledge have so cheapened production that they have succeeded in getting this trade out of the hands which previously controlled it. A great advance has also been made in the scientific instrument industry. The value of the exports from Germany of scientific instruments in the year 1898 was about 250,000*l*.—three times what it was in 1888—and the work gave employment to 14,000 people. These are a few of the many instances showing the close connection between the scientific education of the German people and their commercial prosperity.

The United States Weather Bureau has just issued a paper by Prof. Alfred J. Henry on wind velocity and fluctuations of water level on Lake Erie. Continuous automatic records of the variations of level at Amherstburg and Buffalo for December, 1899, to November, 1900, are correlated with wind records at Buffalo for the same period, and the material applied to analysis of seiches of different types, including the "fair weather" seiches and those accompanying storms. The period of the smaller seiches is about fourteen hours, that of the larger about sixteen hours. The occurrence of a severe seiche at Buffalo cannot be foretold many hours in advance, but sufficient time could generally be given to warn property interests along the wharves.

The report of the Californian section of the climate and crop service of the Weather Bureau, for April, contains an interesting note on a statement in the article on Francis Drake in the "Dictionary of National Biography." Referring to the position of Drake's anchorage near the Golden Gate in June, 1579, the article says:—"The one doubtful point is the account of the climate, which is described with much detail as excessively cold and foggy. (Vaux, pp. 113-118). This is now said to be an exaggeration, but to speak of the climate near San Francisco or anywhere on that coast in July in these terms is not exaggeration, but a positive and evidently wilful falsehood (Greenhow, 'History of Oregon and California,' 1845), credulously inserted by the original compiler of the 'World Encompassed.'" The Weather Bureau station at Point Reyes Light, probably not more than three miles from Drake's anchorage, amply confirms the correctness of Drake's description. Fog is specially prevalent during the months June, July and August, and it is generally accompanied by strong north-westerly winds, often reaching a velocity of fifty miles an hour; a comparison of the records with those from the stations at San Francisco and on Mount Tamalpais shows an astonishing contrast as regards temperature, relative humidity and duration of sunshine. Prof. George Davidson, who was in charge of the work of the Coast Survey in this region, and has published a paper on the "Identification of Sir Francis Drake's Anchorage on the Coast of California," says "that from July 2, 1859, the fog hung over the promontory of Point Reyes for thirty-nine consecutive days and nights."

In an article in Nature of April 18, 1901, attention was directed to the commercial uses made of peat in Sweden, where it is coming largely into use as a substitute for coal for steam engines. In a recent number of the *Engineer* (June 27) an account is given, with illustrations, of the peat fuel works at Stangfiorden, in Norway, where electricity generated by water power has been in use since 1898 for the manufacture of peat for fuel, which is of the more interest because it is reported that negotiations are now in progress for the introduction of this system for the development of one of the water powers on the west coast of Ireland. So far peat fuel and moss litter are the only two products that have been obtained from a very limited number out of the numerous peat bogs to be found in this and other countries. The chief difficulty in manufacturing peat fuel is the extraction of the water, which comprises about 85 per cent. of the whole bulk, and which must be removed before the remaining carbonaceous matter can be rendered available for fuel. At Stangfiorden the wet peat is brought direct from the bog to the factory in boats of 100 tons capacity; the material is removed from these by electric agency and submitted to a preliminary operation of drying and pressing. The briquettes thus formed are then transported on small iron trolleys with shelves to the interior of the drying chamber. Warm air is driven through this by electric fans. From the drying chamber the blocks are taken on the same trolley to the retorts, where they are packed round spiral resistance coils and the electric heating agent set in operation. The peat yields—besides the fuel briquettes, which form 33 per cent. of the whole—tar, charcoal, creosote, sulphate of ammonia and other bye-products. The electric power is derived from five 80-kilowatt dynamos coupled direct to five turbines of 128 H.P. The plant is capable of turning out 1000 centners of air-dried peat a day. The fuel burns well, yields little soot or ash, and is readily disposed of in Bergen and other towns.

From a paper communicated by Prof. Höfer to the Vienna Academy of Sciences it appears that spring waters from a large number of different petroleum districts either contain no sulphates or at most a minimal quantity of these salts. Under the influence of the petroleum and marsh gas, the sulphates have probably undergone reduction. It is pointed out that the absence of sulphuric acid in waters from petroleum provinces may be advantageously made use of in a practical way for ascertaining the whereabouts of petroleum deposits or inversely for determining the source of the waters in question.

Messrs. Sanders and Crowhurst have sent us a catalogue of the photographic apparatus which is made and sold by them. The list contains almost everything that a photographer can desire; many useful novelties are included.

Messrs. A. W. Penrose and Co. are making Mr. Alex. Tallent's diffraction spectroscope camera, an account of which instrument is given in a small pamphlet published by Messrs. Penrose. The main feature of this camera is that we have in a small compass a light, compact, handy and inexpensive spectroscope, ready for use at any moment. Such an instrument is rendered possible only by the introduction of the Thorp diffraction prism-grating, which does away with the necessity of a train of prisms to obtain large dispersion and what is also an important item, the outlay of considerable expense. The compactness of the instrument is due chiefly to the fact that the prism-grating forms a direct vision system. The instrument, a full account of which is given in the pamphlet, only costs from forty-five to sixty-three shillings, according to the requirements of the user, and will be found very serviceable in many directions, such as the composition of various light sources, colour sensitiveness of plates, examination of dark-room filters, &c. The plate which accompanies the text describes better than words the different uses to which the instrument can be applied, and the scale on which the spectra are obtained.

A comparative study of the permeability of living and dead animal membranes by measurement of the electrolytic resistance has recently been made by Mr. G. Galeotti, and the results are published in *Lo Sperimentale, Archivio di Biologia norm. e patol.*, vol. lvi. The living membranes were first investigated, and then after remaining in chloroform vapour for some time were again placed in the electrolytic cell and the resistance of the solution measured as before. Various salt solutions were employed, the strengths of these being in the majority of cases one-tenth normal. The author finds that the resistance of membranes, which in the animal body separate solutions of different nature and concentration from one another, is ten to forty times greater in the living condition than when the membranes are dead. The resistance of membranes, which have no functions of this character in the animal system, is, on the other hand, unaltered by the action of chloroform vapour. The conclusion is drawn that membranes of the first class, for example, from the cæcum of the rabbit and the bladder of the turtle, behave as semipermeable membranes in the living condition, but this semipermeability is lost when the cells are dead. Membranes of the second class, on the other hand, act simply as diffusion membranes, and the permeability of these is the same whether living or dead.

ALTHOUGH the question as to whether the nitrogen of the albuminates present in the animal body is partly set free in the form of free gaseous nitrogen has been experimentally studied on several occasions, yet the conclusions drawn by different investigators working under different conditions are by no means concordant. The first series of such investigations was carried out by Regnault and Reiset, who found, in the great majority of their experiments, a considerable increase in the quantity of nitrogen in the respired air. About one hundred experiments were made and animals of totally different classes were subjected to investigation. Seegen and Nowak, with an improved apparatus which permitted of the experiments being continued over much longer periods of time, obtained results which agreed with those of the first observers. Hans Leo, working under different conditions, concluded, on the other hand, that nitrogen, as a product of the decomposition of albuminates, is not set free from the animal system. In Leo's latest experiments, the bodies of the animals under investigation were immersed in water, and under these conditions it was found that the alteration in the amount of nitrogen of the air was scarcely perceptible. To promote the further investigation of this subject, Prof. J. Seegen has placed 6000 kronen at the disposal of the Vienna Academy of Sciences, which sum is offered by the Academy as a prize for the solution of the question. The formulation of the problem reads:—"Es ist festzustellen, ob ein Bruchtheil des Stickstoffes der im thierischen Körper umgesetzten Albuminate als freier Stickstoff in Gasform, sei es durch die Lunge, sei es durch die Haut ausgeschieden wird." Papers sent in for competition are to be written in German, French or English, and should be sent to the office of the Academy before February 1, 1904.

THE *American Naturalist* for June contains an article, by Mr. W. R. Coe, on the Nemertean worms parasitically infesting certain crabs, in the course of which the new genus Carcinomertes is described.

MODERN refinements of description render it of the utmost importance that skins of small mammals should be made up on one uniform plan. Mr. G. S. Miller has accordingly published in the *Bulletins* of the U.S. Museum a revised edition of directions for making such preparations, with abstracts in German, French and Spanish.

AMONG other articles, part 4 of vol. lxxi. of the *Zeitschrift für wissenschaftliche Zoologie* contains one by Dr. K. Escherich on the development of the nervous system in flies, and a second, by Prof. P. Bachmetjew, on the effects of heat on the development of the pupæ of butterflies and moths. The nerves of the skin form the subject of a third communication, by Dr. Tretjakoff.

THE thoroughness of American methods is well exemplified in a review of the horned larks (Otocoris), by Mr. H. C. Oberholser, forming No. 1271 of the *Proceedings* of the U.S. Museum. In addition to four maps illustrating the distribution and breeding areas of these larks, this memoir contains photographs showing the different kinds of country inhabited by the various local races of certain species. These birds vary so much according to environment that their classification and identification are the despair of the systematist. The manner and degree of this variation—and not the mere identification of specimens—should be the aim of the investigator.

IN the June issue of the *American Naturalist* Mr. J. F. McClendon describes the life-history of the insect commonly known as *Ulula hyalina*, a near relative of the so-called ant-lion of Europe. The larva "hides in some slight depression or under the edge of a stone, with its body covered with sand and its mandibles widely extended so as to touch the fringe of hairs on each side of the head. Its brown colour simulates the colour of the sand. Its body is hidden by the covering of sand, and the head is somewhat concealed by its peculiar covering of hairs, so that small insects may crawl, unawares, too near the extended mandibles. In this case the larva thrusts out its head and snaps the mandibles together, pinioning the victim on the curved points. It then proceeds to suck out the juices of its prey like an ant-lion."

AN appendix to the twentieth annual *Report* of the Scotch Fishery Board contains notes on the digestive tract of salmon and sea-trout kelts from the Tweed by Mr. J. K. Barton, illustrated with some beautiful reproductions from photographs of microscopic preparations. The author is of opinion that sea-trout continue to feed to within a shorter interval of their entering fresh-water than is the case with salmon, although when in the rivers both fishes are equally abstemious. No trace of the desquamative catarrh of the mucous coat which has been supposed to characterise the intestines of river fish was observed. It must be left for subsequent examinations to determine whether salmon-disease is due to the fungus Saprolegnia, or whether the presence of that fungus is merely the precursor of death owing to other diseased conditions.

MUCH interest attaches to an article in the *American Naturalist* for June on aggregated colonies in madreporiform corals, by Dr. J. E. Duerden. The fact that coral larvæ will occasionally attach themselves to the cups of adult corals of the same species has been noticed by previous observers. The author finds, however, that in certain West Indian corals an analogous process is quite a common method of formation of composite corals, the larvæ of Siderastræa frequently fixing themselves close together in small groups upon some convenient base. In course of time they grow together to form a colony, which thus differs from an ordinary colony in consisting of several individuals. Such an aggregate colony may be distinguished, for a time at least, from one of the ordinary type, by the fact that the component items are not in communication at the base.

THE search for the missing link forms the subject of an article, by Mr. R. S. Baker, in this month's *Idler*, mainly based on the discovery of "Pithecanthropus" and Prof. Haeckel's expedition to Java in search of further remains of that mysterious creature. The author traces the gradual "evolution" of the conception of the origin of one group of animals from another, and illustrates his subject with excellent portraits of Darwin, Haeckel, Huxley and Wallace. We are afraid that the illustrated table of man's descent will be apt to prove a stumbling-block to the uninitiated, and that the gorilla, gibbon, opossum, iguana, &c., will be regarded as among man's direct ancestors. The inclusion of marsupials in man's genealogical tree is, we fear, an error which it will take some time to eradicate from popular writings. The author would have done well to have shown his proof to some zoological friend, which would have resulted in the elimination of the sentence as to the association of Pithecanthropus with *the* elephant, rhinoceros, hyæna, &c. What may be the animal designated in the same sentence as "the gigantic pangolin" we are at a loss to conceive.

A BRIEF summary of progress in archæological and ethnological research in the United States during last year is given by Prof. F. W. Putnam in a reprint from vol. xiv. of the *Proceedings* of the American Antiquarian Society (1901, pp. 461–470). Since the paper was read at the annual meeting of the Society in October 1901, the Carnegie Institute has been founded at Washington, and the broad spirit in which it has been organised gives satisfaction to all who are anxious to extend

the boundaries of scientific knowledge. Referring to the Institute, Prof. Putnam remarks: "The scope of this foundation embraces all the sciences, and its purpose is the encouragement and patronage of research. Such an institution will have the power to render incalculable service to American archæology and ethnology, where so much needs to be done without loss of time."

WE have received the first two numbers of a series of occasional reports on the agriculture and forest culture of German East Africa, issued by the Central Government at Dar-es-Salam, and published by Carl Winter at Heidelberg. These reports, which are to be continued as occasion requires, contain the results of valuable scientific investigations by officials, dealing with such matters as the tse-tse fly, analyses of soils, climatology, &c. Extracts of reports from numerous civil and military stations are given, and accounts of exploring journeys into less-known regions of the colony.

THE current issue of the *British Medical Journal* (July 5) is a special vaccination number, and contains several interesting contributions on Jenner's life and works, and on small-pox and vaccination. Much valuable material—scientific, clinical and administrative—connected with the disease and its remedy, is described by writers of recognised authority.

MESSRS. DUCKWORTH AND CO. will publish immediately a book on "European Fungus-Flora," by Mr. George Massee, principal assistant at the Royal Herbarium, Kew. The work will be a synopsis of the European Agaricaceæ, giving the specific characteristics of 2750 European species, of which 1553 are British.

MESSRS. DAWBARN AND WARD have commenced the publication of a series of practical handbooks designed to be of service to dwellers in the country. The first book of the series, on "Outdoor Carpentry," by Mr. S. Walter Newcomb, gives brief instructions, with plans, sketches and details, for constructing rustic work of many kinds. Among the subjects of future volumes will be water-supply and distribution, sanitation and drainage, and planning gardens, grounds and outbuildings.

THE *English Illustrated Magazine* for July contains an article upon the supposed portrait of Christ on the Holy Shroud of Turin, translated from the French, and based upon Dr. Vignon's work on "Le Linceul du Christ." The article leaves the question whether the markings upon the shroud were really produced by the body of Christ undecided, but it is held that there is sufficient evidence for the belief that the image was naturally imprinted upon the shroud by the action of vapours arising from a human body. Another article in the magazine, by Mr. J. J. Ward, gives an instructive illustrated account of May-flies and related insects.

THE "Technolexicon," or technical dictionary, to be published by the Society of German Engineers, has previously been referred to in these columns. The editor, Dr. Hubert Jansen, Berlin (N.W. 7), Dorotheenstr. 49, is anxious to include in the dictionary all technical terms used by French, German and English engineers, so that the dictionary shall contain equivalent words and expressions in each of the three languages. Collaboration is invited from societies, individuals and engineering works. The editor would be glad to receive technical catalogues, price lists, hand-books, or lists of words and terms for which correct renderings cannot be found in ordinary dictionaries. The work will be so useful when ready that all who are able to contribute to its completeness should do so.

THE additions to the Zoological Society's Gardens during the past week include two White-eared Conures (*Pyrrhura leucotis*) from Brazil, presented by Lady Lindsay; two Peregrine Falcons (*Falco peregrinus*), European, presented by Dr. R. Lawton Roberts; a European Pond Tortoise (*Emys orbicularis*), European, presented by the Earl of Dudley; a Common Viper (*Vipera berus*), British, presented by Mr. E. Ball; two Snowy Egrets (*Ardea candidissima*) from America, two Vinaceous Amazons (*Chrysotis vinacea*), two Red-tailed Amazons (*Chrysotis brasiliensis*) from Brazil, seven Roofed Terrapins (*Kachuga tectum*) from India, a Black Sternothere (*Sternothoerus niger*) from West Africa, a Wrinkled Terrapin (*Chrysemys scripta rugosa*) from the West Indies, a Blue-tongued Lizard (*Tiliqua scincoides*) from Australia, a Madagascar Tree Boa (*Corallus madagascariensis*) from Madagascar, deposited; a Proboscis Monkey (*Nasalis larvatus*) from Borneo, two White Storks (*Ciconia alba*), European, purchased.

OUR ASTRONOMICAL COLUMN.

THE PERIODICAL COMET OF TEMPEL-SWIFT (1869-1880).—This object is one of the most interesting of the somewhat numerous class of comets which at aphelion pass just outside the orbit of Jupiter and perform their revolutions in periods ranging from about 5 to 9 years. First seen by Tempel in 1869 November 27, the character of the orbit was not determined until its independent discovery by Lewis Swift in 1880 October 10. It was then found to be moving in an orbit of short period for the elements deduced by Bruhns, for the apparition of 1869 very closely resembled those obtained by Chandler for the return of 1880, and the latter pointed out the true character of the orbit early in 1880 November. Messrs. Schulhof and Bossert, of Paris, also published elements indicating a periodic time of $5\frac{1}{2}$ years.

The average period for the four returns which occurred between 1869 and 1891 was 2009 days, or 5 years and 183 days. At every alternate return, however, the comet is invisible. The perihelion is reached at a distance of about 10,000,000 miles outside the earth's orbit, and the three previously observed perihelion passages having occurred between November 6 and 18, the conditions were extremely favourable, the longitude of the comet's perihelion being 43° and the longitude of the earth on November 6 being 43°. The comet and earth were, in fact, mutually situated in or near those parts of their orbits which make the nearest approach to each other. At alternate returns such as in 1875, 1886, 1897, 1908 and 1919, the earth is on the opposite side of the sun to the comet when the latter passes through perihelion. In such circumstances the object is altogether beyond reach, for at one of these unfavourable returns it is placed nearly 200,000,000 miles from the earth, whereas under the best conditions, similar to those which prevailed during the apparition in 1880, the distance may be less than one-tenth of that mentioned.

As in 1869, 1880 and 1891, so in 1902, the comet will be very favourably visible in the autumn and winter months, and it will probably be re-detected in one of our large telescopes in about September next. The object will be by no means conspicuous, nor is it likely to display any attractive variety of aspect, but any moderately good telescope will show it as a large faint nebulosity. One of the best known of the ever-increasing group of Jovian comets, it will be sure to attract considerable attention during its forthcoming return, not so much, perhaps, on account of its visible characteristics as from the example it affords of a numerous class of bodies and from the interesting history attached to its previous appearances.

MR. TEBBUTT'S OBSERVATORY AT WINDSOR, N.S.W.—The annual report of this observatory for 1901 shows that much useful work was done last year. Measures of the positions of Venus, Ceres, Parthenope, Melpomene and Diana were made and the results forwarded to the *Astronomische Nachrichten* (Band clvi. p. 105).

Under "Comet Observations" we find that 273 determinations of the position of Comet I. 1901 were made between May 3 and June 13, 1901, and the full results were published in the *Astronomische Nachrichten* (Band clvi. p. 95 and Band clvii. p. 187). Encke's comet was fruitlessly sought on the evenings of October 2 and 8.

During twenty evenings the measures of twenty-eight double stars were made and the results published in the *Monthly Notices* R.A.S. (vol. lxi. p. 51).

The tables of meteorological observations show a temperature above, and a rainfall below the average, the year 1901 being the driest year recorded (excepting 1888) since 1862.

Many astronomers will regret the necessity for the inclusion of the following paragraph in the report, for it announces a great loss to observational astronomy generally, and especially to that of the southern hemisphere :—"In consequence of the author's advancing years, it is probable that there will be a considerable relaxation in his efforts for the year 1902."

EXTENSION OF THE KATHODE RADIATION HYPOTHESIS TO NEBULÆ.—At the meeting of the Académie des Sciences held on June 23, M. Janssen presented a note from M. Deslandres, in which the latter extends the kathode ray hypothesis, which he had already proposed in order to explain solar phenomena, to nebulæ.

The author says that the hypothesis of Arrhenius which attributes the light emitted by nebulæ to electrified particles, and also that of Nordman which attributes it to Hertzian rays gathered from space, are both wrong, for if they were true, the terrestrial atmosphere itself would, at night-time, display similar light; therefore, he adds, the light must be in the nebulæ themselves.

PERSONAL EQUATION IN THE MEASUREMENT OF SPECTROSCOPIC NEGATIVES.—In a note to the *Memorie della Società degli Spettroscopisti Italiani*, M. Hasselberg makes some interesting statements on the part that the personal equation of the observer plays in the measurement of photographic spectra. Quoting the note on this subject, by Mr. Reese, in *The Lick Observatory Bulletin*, No. 15, wherein it was demonstrated that the tendency in the case of Mr. Reese was to place the dark lines of the spectrum negative, as contrasted with the bright lines, a little too much to the right of the field of the microscope, M. Hasselberg goes on to demonstrate that in his own case the tendency is exactly opposite. Consequently, he finds that, in general, his personal equation makes his wavelengths come out systematically less than those published by Rowland for the same lines.

The author gives three sets of measurements of metallic spectra which he has observed, compares them with the analogous values obtained by Rowland, and, after meaning the differences to eliminate accidental errors, he finds that there remains a systematic difference of $\pm 0{\cdot}007$ Angstrom units, and this he ascribes to purely physiological causes.

In the third table given by M. Hasselberg he compares his measurements of the lines in the tungsten spectrum: (1) when the lines are brought to the centre of the field from the left to the right, and (2) when they are brought to the centre from the right to the left, and here he finds that in the first case his values are too great, whilst in the second case they are too small.

The author concludes by pointing out that, although these errors are very small, yet they are too pronounced to be neglected, and shows that by a curious coincidence his personal error would, if introduced into the determination of radial velocities, produce a difference of exactly 1 kilometre per second from the true velocity.

APPARENT DEFORMATIONS OF THE SUN'S DISC NEAR THE HORIZON.

ALTHOUGH curious deformations of the apparent shape of the sun and moon near the horizon have been noticed from the earliest times, observations are not very frequently made, and the apparent changes of the appearances of these bodies when near the horizon cannot be said to be very commonly known. Among the earliest descriptions of this phenomenon may be mentioned one during "The strange and dangerous voyage of Captaine Thomas James, in his intended Discovery of the Northwest Passage into the South Sea," London, 1633. He states:—"I obserued the Sunne to rise like an Ouall, alongst the Horizon: I cald three or foure to see it, the better to confirme my Judgement: and we all agreed, that it was twice as long as it was broad." On March 26, 1632, James observed the same phenomenon at the time of the rising of the moon. Biot, in his "Traité élémentaire d'Astronomie physique," writes:—"C'est encore par un effet de la réfraction atmosphérique que le Soleil à l'horizon paraît ovale et aplati dans le sens vertical, même dans les temps les plus calmes et les plus sereins. Tous les points de son disque sont alors élevés par l'effet de la réfraction, mais ils le sont inégalement: les points inférieurs le sont plus que les supérieurs, parce qu'ils sont plus près de l'horizon, ou la refraction est plus forte. Le disque du Soleil doit donc alors sembler aplati, dans le sens vertical."

Among more recent papers upon this phenomenon may be mentioned one by Lieut. F. Křifka, entitled, "Refractionserscheinungen der aufgehenden Sonne" (*Meteorologische Zeitschrift*, 1891, p. 101). During the trigonometrical survey of Brno in Bohemia, Colonel von Sterneck directed attention to the remarkable shape of the rising sun, and careful observations were taken by himself with a telescope, and by Lieut. Křifka with the naked eye, until the sun rose above the horizon. Illustrations are given of the shape and colour of the sun during fifteen phases; the colour was first a deep red and gradually faded into yellow as the sun regained its globular appearance. The forms were very curious, some resembling a basin with a projecting lid; others appeared very much like the shape of a mushroom, with its stalk; later, an oval shape was assumed.

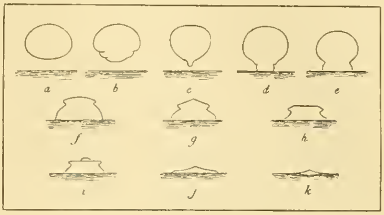

FIG. 1.

During the voyage of the Belgian Antarctic ship *Belgica*, M. H. Arctowski, a member of the scientific staff, made frequent observations of the phenomenon in question between Rio de la Plata and the Straits of Magellan, both when the sun was rising and setting, and he has communicated the results in an interesting paper published in the *Bulletin* de la Société belge d'Astronomie, accompanied by outline sketches. The description given of the phenomenon seen on November 23, 1897 (Fig. 1), off the coast of Patagonia is typical of other observations. On approaching the horizon the lower portion of the sun became flattened, and continued to become more deformed as it descended. At about 3° above the horizon there was a thin film of cloud, and the part of the sun which was still above the level of this little cloud preserved its regular shape. Gradually the lower part assumed a triangular shape, a little point or stem appeared, and became enlarged as it touched the horizon. The sketches show that all the zone comprised between the fine belt of cloud and the horizon possessed the property of deforming the sun's disc, and that in every case the cloud was the principal seat of the deformations. After the sun had set it was scarcely possible to see the cloud. The sketches very closely resemble the Bohemian illustrations already mentioned.

FIG. 2.

The accompanying figure (Fig. 2) is a reproduction of a photograph showing deformation of the setting sun, taken by Prof. W. Prinz, of the Royal Observatory of Belgium, at Uccle, near Brussels, and communicated to the *Memorie della Società degli Spettroscopisti italiani*, by Prof. A. Riccò. The dark background is drawn exactly circular, in order that the deformation of the sun's disc may be seen more clearly. In this case the ratio of the vertical to the horizontal diameter is $75 : 84$ mm. $= 0{\cdot}893$.

OCEANOGRAPHICAL INVESTIGATIONS IN SOUTH AFRICAN WATERS.[1]

THE observations published in the pamphlet of which the title is given below are the first of a series undertaken in connection with the fishery investigations recently inaugurated at the Cape. They include observations made in March and April, 1900, by the Government steamer *Pieter Faure*, consisting of temperatures and analyses of water samples from points to the west of the Cape Peninsula; observations of surface temperature made on February 11 to 18 and March 3, 1898, at intervals of about five miles, to a distance of fifty miles west of Cape Town, and on a voyage to St. Helena Bay; daily records of air and sea temperatures taken at Robben Island in Table Bay, and at Roman Rock in Simon's Bay during the three years 1898–1900; temperatures and analyses of water samples taken at intervals on passages of the Government trawler between Table Bay and Simon's Bay, and of mail steamers between Table Bay and Cape Hangklip. An extended series of observations is now in progress over the whole of the South African coast.

The investigation of which this forms the beginning is, without doubt, one of the most valuable and important of its kind ever attempted. The preliminary international work which has been carried on in the North Sea and the Baltic during the last nine years, and is now about to take definite shape as an organised system of research, has shown that adequate hydrographical observations are of the utmost value, not only in themselves as determining the circulation of waters, but in their relation to climatology and to fishery work of all kinds. Similar research in South African waters has the additional interest of dealing with a region where the current system is not only unusually complex, but is very strongly and clearly developed; and the fact that the services of a special ship are available renders the opportunity of studying the relations existing amongst the different current elements unique.

Unfortunately, however, the methods employed in the present series of observations seem to leave much to be desired. Nothing is said about the thermometers employed in taking temperatures, or about their corrections, and the observations at different depths are made with little reference to the changes of temperature; many of them are unnecessary, and there are frequent gaps which leave the true form of the temperature curve undetermined. The curves and sections shown suggest that the boundaries between masses of water are often very sharply defined, and that a high degree of accuracy, in the instruments employed, in their working, and in the determinations of ship's position, is essential. The laboratory analyses of the samples of water collected are still more unsatisfactory. In most cases the chlorines have been determined, by a method not stated, and the results are, for a reason left unexplained, expressed in grains per gallon, thereby rendering them incomparable with any other determinations except those of county analysts. A study of the chlorine values in relation to their geographical distribution does not inspire confidence in the accuracy of the determinations, and the uncertainty increases on comparison with the values in columns headed "specific gravity" and "sulphuric oxide." No account is given of the methods by which the specific gravity determinations have been made, nor is there any statement as to the temperatures to which they are referred, and we find, for example, such records as the following:—

Temp. °F.	Specific gravity.	Chlorine in grains per gallon
63·0	1·02712	1412·0
63·0	1·02696	1414·5
63·0	1·02700	1409·5
63·0	1·02700	1422·0
63·0	1·02696	1402·0
63·0	1·02723	1414·5

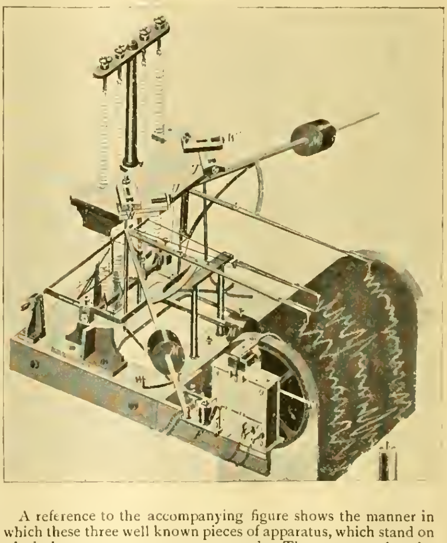
The determinations of sulphuric oxide, which are, presumably, also stated in grains per gallon, give, on a series of averages (p. 215), values of the chlorine ratio ranging from 11·8 to 12·2, and on a single set (p. 213) from 10·4 to 13·1. Such determinations fall distinctly short of the standard required for work of the kind, and as there is no continuity in the variations, we must regard the whole of the tabular matter in the paper with considerable suspicion. Finally, we note that in a region where meteorological observations are of the greatest interest and value, a specially equipped scientific expedition makes its barometer readings "direct from Aneroid."

We direct attention to these points because the importance of the work imperatively requires that it should be thoroughly well done when there is an opportunity of doing it at all. The detailed reports on methods, published by participants in the international work already mentioned, and the tables produced by Knudsen under the direction of the International Committee, leave no excuse for doing it otherwise.

[1] "Cape of Good Hope. Department of Agriculture. Marine Investigations in South Africa. Observations on the Temperature and Salinity of the Sea around the Cape Peninsula." By J. D. F. Gilchrist, M.A., B.Sc., Ph.D.

A NEW FORM OF SEISMOGRAPH.

IN the *Bollettino della Societa Sismologica Italiana* (vol. vii. No. 7), Dr. G. Agamennone gives a detailed description of a seismograph, consisting of two horizontal pendulums each of which carries a mass of 1½ kg. and a vertical spring seismograph with a mass of 2 kg., which write their records side by side on a band of smoked paper 25 cm. broad.



A reference to the accompanying figure shows the manner in which these three well known pieces of apparatus, which stand on a bed plate 55 cm. square, are arranged. The screws W alter the inclination of the vertical axes of the horizontal pendulums and hence their period. The screws U are to give horizontal adjustment for the same. By shifting the position of the weights MM, assuming the same to coincide with centres of oscillation, the multiplication of the writing pointers, which are at the extremities of arms attached at 45° to those carrying the weights, may be made twice that of the movement of the ground. It is almost needless to remark that with so small an amplification the instrument is only intended to record earthquakes which can be felt and are severe. When such an earthquake occurs, the electromagnet F is brought into action to release the clockwork, and the smoked paper then moves beneath the writing pointers at a rate of 25 metres per hour—a speed sufficiently high to give an open diagram of vibrations with periods of 1 10th second. But is it not desirable to record vibrations with a frequency greater than 10 per second, and in addition to obtain a trace of the preliminary tremors? Dr. A. Cancani, who uses films which move continuously at a rate of 6 metres per hour, obtains something to show the latter, but the rate is not sufficiently high to give open records of movements the period of which is very short. Then again, it must not be overlooked that the large movements of severe earthquakes are undulatory in character, and both horizontal pendulums and vertical spring

seismographs are simply swung from side to side or up and down under the influence of the tilting of their supporting bed plate.

Dr. Agamennone's new arrangement will no doubt give records which are valuable, but the seismograph which is suitable to record all forms of earthquake motion has yet to be designed. J. M.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—During the long vacation, beginning on July 7, courses of lectures will be given as follows:—Mathematics and astronomy, by Sir Robert Ball, Mr. Richmond, and Mr. Coates; practical histology, by Dr. Hill and Dr. Barclay-Smith; pharmacology, by Prof. Bradbury and Dr. Dixon; osteology, by Dr. Barclay-Smith; geology, by Mr. Marr; crystallography, by Mr. Hutchinson; chemistry, by Mr. Fenton; metallurgy, by Mr. Dootson; analysis of foods, &c., by Mr. Purvis; practical physics, by demonstrators in the Cavendish Laboratory; pathology and morbid histology, by Prof. Woodhead and Mr. Strangeways-Pigg; bacteriology and preventive medicine, by Dr. Nuttall; animal parasites, by Mr. Shipley; medicine, by Dr. Humphry and Dr. Lloyd-Jones; surgery, by Dr. Griffiths and Mr. Wherry; hygiene, by Dr. Anningson.

THE Nature-Study Exhibition to be held at the Royal Botanic Gardens will be opened on July 23 by the Duchess of Devonshire, the Duke of Devonshire being in the chair. A number of interesting conferences have been arranged in connection with the exhibition. Among the subjects to be brought forward in addresses and short papers are:—"The Study of Nature," by Lord Avebury, F.R.S.; "Seasonal Studies in Natural History," by Prof. J. Arthur Thomson; "Nature-Study in Elementary Schools," by Prof. C. Lloyd-Morgan, F.R.S.; "Visual Instruction," by Prof. Bickmore; "Nature-Study in Colleges and Higher Schools," by Prof. Miall, F.R.S.; "Plant-Life as Nature-Study," by Mr. Scott Elliott; "School Gardens," by Mr. T. G. Rooper; "Geology as a Branch of Nature-Study," by Prof. Grenville Cole; "The Training of Teachers in Nature-Study," by the Rev. Canon Steward; and "The Relation of Nature-Study to School Work and to the Home," by Sir Joshua Fitch.

MANUFACTURERS and others interested in paper-making have been invited to give their support to a scheme for the establishment of special scientific and technical instruction in connection with this industry at the Battersea Polytechnic. It is suggested that the scheme should provide for both day courses (extending over two or three years) and evening classes for employés who cannot be spared during the day; and that it should include thorough and systematic scientific and technical instruction (theoretical and practical) in chemistry and engineering so far as is necessary for the science of the subject and helpful for its practical carrying out, combined with experimental work in a laboratory or workshop specially fitted up for the actual manufacture of paper and complete testing of the finished product. Such a department when organised would naturally become a centre of research in questions connected with the paper-making and cellulose industries. The circular states that the paper-makers in the North of England have taken up the question in a very practical way and are supporting one of the large technical colleges, where they have put down a small model paper machine, which has been made in Germany, no English manufacturer being found willing to undertake the making of it.

THE Calendar of the Tokyo Imperial University for 1901-1902 shows that provision is made for the study of many branches of pure and applied science. In the College of Engineering, practical work and excursions are arranged outside the College, in addition to the laboratory work. In connection with the College of Science there are museums of zoology, geology and anthropology, and a herbarium. At the Astronomical Observatory the principal work carried on consists of observations of position and the compilation of almanacs. The director of the Botanic Garden is prepared to exchange seeds with foreign botanists or institutions. Earth-movements are continually studied at the seismological observatory, and on the occurrence of a great earthquake an expedition is at once sent to make all possible investigations. The Marine Biological Station is situated on the extremity of the peninsula jutting out between the Bay of Sagami and the Gulf of Tokyo; it thus has access to localities rich in remarkable animal forms. Though the station is primarily intended for the use of instructors and students of the University, its facilities are extended to other persons who are qualified to avail themselves of the opportunities of research there afforded. The College of Agriculture is a very active part of the University, and the numerous investigations carried on in the experimental farm have often been noticed in NATURE. Connected with the zoological laboratory of this department are four buildings for the study of silk-worm culture, containing all the apparatus required for experiment and research. Rooms are also provided for special work in the study of the pebrine disease—the most formidable obstacle to silk-worm culture.

SEVERAL matters of interest are mentioned in the report of the Council of the City and Guilds of London Institute, a copy of which has been received. Important extensions have been made at the Central Technical College, among them being additions to the electrical department in order to bring it up to the present requirements of the electrical industry. The total cost of the extension of the College, including equipment and all structural additions and alterations, both for the College and for the department of technology, is estimated at 10,000*l.*, and the additional annual cost at about 1000*l.* The Institute has recently received from the University of London an offer to devote 1425*l.* a year to the department of engineering in the Central Technical College, subject to certain conditions. This amount is the larger part of a grant made to the University by the Technical Education Board of the London County Council for improving and extending the teaching of engineering in the metropolis. It involves the appointment of the professor of engineering of the College as a "transferred teacher" of the University, and it is a recognition by the University that the College occupies the foremost position among engineering colleges in the metropolis. The organisation and work of the College have not otherwise been affected by reason of its inclusion as a school of the University. At the Technical College, Finsbury, the only change recorded in the educational scheme is the addition of a laboratory class in electrochemistry for second-year chemical students. The development of the use of electricity in the chemical industries has shown the necessity of making more complete the training which has been given to chemical students in this branch of physics.

A COPY of an address on the University of London, delivered by Dr. E. H. Starling, F.R.S., at University College, London, on June 5, has been received. Some of the prominent points brought forward in the address have already been described (p. 164), and are the same as those stated in these columns on more than one occasion. What are wanted in London are great University centres, adequate to the higher intellectual needs of the seven million inhabitants. The main features of the University of London sketched by Prof. Starling are as follows:—"Under the control of the Senate, but administered by local councils appointed by the Senate, would be these four or more centres, by which the main teaching and research of the University in all Faculties would be carried out. In addition to these centres there would be a number of *schools of the University* which would preserve their autonomy, but would direct their teaching according to the requirements of the University. Such schools would be essentially post-graduate in character, in that it would be their office to graft on the general training in method, acquired within the walls of the University itself, the special professional training necessary to fit the man for the pursuit of medicine, law, commerce, administration, &c. The relation of the Polytechnics to the University will require careful consideration. In any policy decided upon, it must be remembered that the whole object is the improvement of the mental training of our fellow citizens and not the distribution of degrees. It is vital to the welfare of the country that as many as possible of its inhabitants should have received a thorough university training, and be competent to use their brains in solution of the new problems which must continually meet them, whatever their trade or profession. The whole progress of the nation depends on the mental equipment of its members. At no time more than the present have the words of Bacon on this subject been so full of counsel: 'If any man thinks philosophy and universality to be idle studies, he doth not consider that all professions are from thence served and supplied. . . . For if you will have a tree bear more fruit than it used to do, it is not anything you can do to the boughs, but it is the stirring of the earth and putting new mould about the roots that must work it.'"

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 15.—"A Note on the Recrystallisation of Platinum." By Walter Rosenhain, B.A. (Cantab.), B.C.E. (Melbourne). Communicated by Prof. Ewing, F.R.S.

The author has observed phenomena in platinum analogous to those of recrystallisation in other metals previously described by Prof. Ewing and himself (*Phil. Trans.* A. 1900, vol. cxcv.). It is well known that platinum which has received a prolonged exposure to high temperature becomes brittle and that its surface, if it has been exposed to flame, shows crystalline markings. This has been ascribed to the action of carbon, but the author ascribes it to a process of recrystallisation and subsequent surface etching by the flame. Evidence in favour of this view is drawn from the micro-structure of this "brittle" platinum, from its behaviour on etching with aqua-regia, and from its mode of fracture when hot. The micro-structure is shown to be that characteristic of recrystallised metals, the action of aqua-regia is found to brighten the flame-etched surface, and the fracture follows lines characteristic of the surface crystals, thus proving that the surface pattern truly represents the structure of the whole thickness of metal. The author points out that cold-worked metal is very apt to undergo recrystallisation at high temperatures, and that in several well-known cases brittleness results from such a process; he believes, therefore, that recrystallisation accounts for all the phenomena except the surface markings, and these he ascribes to an etching action of the flame in which the temporary formation of a carbide may play a part.

June 19.—"On an Approximate Solution for the Bending of a Beam of Rectangular Cross-section under any System of Load, with Special Reference to Points of Concentrated or Discontinuous Loading." By L. N. G. Filon, B.A. (Cantab.), M.A., B.Sc. (Lond.), King's College, Cambridge, Fellow of University College, London, and 1851 Exhibition Science Research Scholar. Communicated by Prof. G. H. Darwin, F.R.S.

The paper investigates the elastic equilibrium of a long bar of rectangular cross-section in cases where the problem may be treated as one of two dimensions, the plane of the strain being the vertical plane through the axis of the bar.

General solutions in arbitrary functions are first obtained. These, on being applied to the particular case, lead to series involving hyperbolic sines and cosines. These series, when the length of the bar is made infinite, degenerate into integrals which can be expanded in ascending powers of the radius vector from any point, within a certain circle of convergence. The properties of these series and integrals in the neighbourhood of points of concentrated or discontinuous load are specially considered.

By means of these solutions, arbitrary conditions of stress over the top and bottom faces of the beam can be satisfied.

Various cases, including those of a doubly supported beam carrying a central isolated load, of a block resting upon a smooth rigid plane and pressed by a knife edge on its upper surface, of a beam under two equal opposite loads not in the same straight line, and of a bar under tension produced by knife-edge "grips" on either side, are considered.

The corrections that must be applied to the expressions given by de Saint Venant for stresses in the free parts of long bars, when we approach the points of application of concentrated loads, are investigated at length. It is found that, at distances from the sections where such load is applied of the order of the larger diameter of the cross-section, these corrections, *i.e.* the local perturbations, become insensible.

Finally, solutions in finite terms are discussed, and such a solution is obtained for a beam carrying a uniform load.

Physical Society, June 20.—Prof. S. P. Thompson, president, in the chair.—Mr. G. F. Herbert-Smith exhibited the three-circle goniometer recently constructed for the British Museum from his designs. In this form of goniometer the advantages of the earlier forms are combined: as with the two-circle or theodolite goniometer, a crystal is only once adjusted during the whole of the observations, and as with the one-circle goniometer observations are made in zones, and full advantage may be taken of the zonal characters of crystals and of the simple formulæ depending thereon.—A paper on the heat evolved or absorbed when a liquid is brought in contact with a finely divided solid, was read by Mr. G. J. Parks. Pouillet discovered the fact that when a powder is put into a liquid which does not exert any solvent or chemical action upon it, there is, in general, a rise of temperature. The objects of the present investigation were to obtain a relation between the quantity of heat evolved and the area of the surface exposed, to find the rate of variation of heat evolved with temperature, and to apply to the results the laws of thermodynamics. From the results of his experiments the author states that when silica, sand or glass is brought into contact with water at approximately constant temperature, the heat evolved is proportional to the area of the surface exposed by the solid, and the amount of heat developed per square centimetre is approximately ·00105 calorie when the temperature is near 7° C. Assuming that the phenomenon of Pouillet is reversible, and that it is due to a pressure at the surface of the powder, the author has, by the application of the laws of thermodynamics and the results of his experiments, arrived at the conclusion that at 7° C. the surface-pressure of water and silica diminishes at the rate of 157 dynes per centimetre for an increase of temperature of 1° C. Experiments made at different temperatures indicate that the heat evolved is roughly proportional to the absolute temperature. Experiments were also made which showed a fall of temperature on putting a finely divided solid into mercury.—A paper by Prof. R. W. Wood, on a remarkable case of uneven distribution of light in a diffraction grating spectrum, was read by the Secretary. It is a well-known fact that in the spectra formed by diffraction-gratings the light is unevenly distributed, that is, the total light in any one spectrum will not recombine to form white light. The author has been examining a most remarkable grating in which the drop from maximum illumination to minimum occurs within a range of wave-lengths not greater than the distance between the sodium-lines. In other words, the grating at a certain angle of incidence will show one of the D lines, and not the other. Experiments with polarised light have proved that these anomalies are only exhibited when the direction of vibration (electric vector) is at right angles to the ruling. The paper gives a detailed account of the appearance of the spectra at different angles of incidence when the grating is in air and when it is immersed in different liquids. It is shown that the phenomena are not due to interference between disturbances coming from widely separated lines, and the author suggests that the matter must be referred to the form of the groove.—A paper by Prof. R. W. Wood, on the electrical resonance of metal particles for light waves (second communication), was read by the Secretary. In a previous paper the author has shown that granular deposits of the alkali metals exhibit brilliant colours by transmitted light. These colours were referred provisionally to the electrical resonance of the minute particles for light waves. The present paper gives an account of experiments made with gold and silver films to determine whether the resonance is molecular, or whether it is an electrical vibration of metallic masses, smaller than the light waves, though of the same order of magnitude. Further investigations on the dispersion of the films and a more careful study with polarised light will doubtless throw light on the matter.—Prof. H. L. Callendar showed a simple apparatus for measuring the mechanical equivalent of heat.

Royal Microscopical Society, June 18.—Dr. Henry Woodward, F.R.S., president, in the chair.—The secretary read a note from Mr. Nelson on some high-power photomicrographs of *Pleurosigma angulatum*, *Surirella gemma* and *Coscinodiscus asteromphalus*, taken by Mr. F. E. Ives.—Mr. A. Hilger exhibited a new photo-measuring micrometer attached to a microscope designed specially for accurately measuring the distances between the lines of the spectrum, but it could also be used for various laboratory purposes.—Messrs. Watson and Sons exhibited and described a new two-speed fine adjustment for microscopes. They also exhibited a microscope fitted with a new holder by which metallurgical specimens could be held in any position while under examination.—Messrs. Carl Zeiss exhibited their epidiascope, a projection apparatus by means of which large brilliantly illuminated pictures of objects can be shown on a screen. Objects such as ordinary lantern slides and transparencies up to 9 inches square, opaque objects, such as photographs, drawings, prints, bones, medals, butterflies in their natural colours, &c., were shown in illustration of its capabilities. A simplified form of microscope was then attached to the instrument, and micro-slides were projected on the screen, giving pictures about 6 feet diameter, with great brilliancy and sharpness of definition.—Prof. Marcus Hartog gave a short

account of the structure of Acinetines, from observations on a species (*Choanophrya infundibulifera*) epizoic on Cyclops. He demonstrated that the spiral marking of the tentacles was due to a double-threaded constriction, that in protrusion and retraction there was no torsion, but only an opening and closing of the spiral, and that the tentacles were continued deep into the endosarc of the creature. —Mr. C. F. Rousselet read his paper on the genus Synchæta, with a description of five new species.—Mr. Walter Wesché gave a brief *résumé* of his paper on undescribed palpi on the proboscis of some dipterous flies, with remarks on the mouth-parts in several families. Specimens showing the palpi on several species were exhibited under microscopes.

Zoological Society, June 17.—Prof. G. B. Howes, F.R.S., vice-president, in the chair.—Mr. R. I. Pocock exhibited and made remarks upon the nest of a gregarious spider (*Stegodyphus dumicola*) sent home by Captain Barrett-Hamilton from Vredefort Road, Orange River Colony, South Africa.—Mr. Oscar Neumann exhibited specimens of some new and interesting mammals which he had discovered during his recent journey through Eastern Africa, and called special attention to some monkeys of the genus Cercopithecus, and to various species of hyraxes (Procavia).—Dr. Walter Kidd read a paper on certain habits of animals as traced in the arrangement of their hair. It was an attempt to interpret, in terms of certain characteristic habits, the departures from a primitive type of hair-arrangement. Short-haired mammals, chiefly ungulates and carnivores, were considered. The habits referred to were divided into passive (those of sitting and recumbent postures) and active (chiefly those of locomotion), and these were shown to match closely the variations observed in the direction of hair in the animals concerned.—Mr. F. E. Beddard, F.R.S., described the carpal organ which he had observed in a female specimen of *Hapalemur griseus* that had lately died in the Society's Gardens. He pointed out that this organ in the female differed in some details from that in the male.—Mr. R. I. Pocock read a paper on some points in the anatomy of the alimentary and nervous systems of the false scorpions of the order Pedipalpi.—A communication from Mr. H. J. Elwes, F.R.S., called attention to Mr. Lydekker's recently published description of a new elk, *Alces bedfordiae*, based on some unpalmated antlers and a skull of an elk from Siberia, and offered a remark that he thought it unadvisable to found a new species, or even a subspecies, on the material. Mr. F. E. Beddard, F.R.S., read a paper, prepared by himself and Miss Fedarb, descriptive of a new cœlomic organ in the earthworm, *Pheretima* (*Perichaeta*) *posthuma*, which consisted of a series of sac-like structures on the floor of certain segments in the middle of the body.—Mr. Beddard also described some new species of earthworms belonging to the genus Polytoreutus, and made some remarks on the spermatophores of that genus.—A communication from Miss Igerna B. J. Sollas contained an account of the Sponges obtained during the "Skeat Expedition" to the Malay Peninsula in 1899-1900. The collection contained examples of twenty-nine species, eleven of which had proved to be new and were described in the paper.—Mr. G. A. Boulenger, F.R.S., enumerated the eight species of fishes of which specimens were contained in a collection made Mr. S. L. Hinde in the Kenya district of East Africa. Four of them were new and were described by the author.—A communication from Mr. A. L. Butler contained a list of the species of batrachians —thirteen in number— that had been added to the Malayan fauna since the publication, in the Society's *Proceedings* in 1899, of Captain Flower's paper on the reptiles and batrachians of the Malay Peninsula.

Geological Society, June 18.—Prof. Charles Lapworth, F.R.S., president, in the chair.—The Great Saint-Lawrence-Champlain-Appalachian fault of America, and some of the geological problems connected with it, by Dr. Henry M. Ami. The extent, earth-movements and striking characteristics of this fault-line and of the geological formations which occur along this line of weakness in the earth's crust, with special reference to the formations in British North America, were discussed.—At this stage of the proceedings, Mr. E. T. Newton, F.R.S., took the chair at the president's request.—The Point-de-Galle Group (Ceylon): Wollastonite-Scapolite-Gneisses, by Mr. A. K. Coomaraswamy. The chief rock-types vary from basic pyroxene-sphene-scapolite-rock, through intermediate rocks composed of pyroxene, scapolite and wollastonite, with felspar and quartz subordinate or abundant, to acid types made up of orthoclase-microperthite or coarse-grained quartzo-felspathic rocks. They differ in several respects from the normal types belonging to the Charnockite series.—On the Jurassic strata cut through by the South Wales direct line between Filton and Wootton Bassett, by Prof. S. H. Reynolds, and Mr. Arthur Vaughan. In this section a thin bed of typical Cotham Marble is followed by the "White Lias," and that by the Lower Lias, which in this district attains a thickness of about 200 feet.

Linnean Society, June 19.—Mr. W. Carruthers, F.R.S., vice-president, in the chair.—Dr. W. G. Ridewood described a new genus of Copepoda occurring parasitically in the suprabranchial cavity of the lamellibranch Lyonsiella, and for which, on account of the great inflation of the thorax, he proposed the name Obesiella. He showed that the systematic position of Obesiella was next to Ascomyzon, in the family Ascomyzontidæ.—Mr. George Massee described some of the results of modern methods of investigation in mycology, illustrating his remarks by means of lantern slides. He pointed out the errors of some observers who urged the suppression of genera wholesale on the evidence of a few species, and pleaded for the retention of familiar names until a clear case for their suppression had been established on evidence furnished by pure cultures.—Mr. W. P. Pycraft read the second part of his contribution towards our knowledge of the morphology of the owls. This dealt with the osteology. After drawing attention to the close resemblances between the skeleton of the striges and that of the accipitres among the falconiformes, and pointing out the homoplastic character of these resemblances, he proceeded to discuss briefly the more important characters of the several genera, and of the nestling skull, which exhibited some curious relations between the squamosal, parietal and alisphenoid bones. The modifications referred to appear to fall under two heads. Especial stress was laid upon the relations of the squamosal. In some forms this bone was barely visible in the inside of the skull, whilst in others almost its entire inner surface was exposed, thus taking a prominent part in the formation of the cranial cavity.

PARIS.

Academy of Sciences, June 30.—M. Albert Gaudry in the chair.—On the structure and history of the lunar crust, remarks suggested by the fifth and sixth numbers of the photographic atlas of the moon, published by the Observatory of Paris, by MM. Loewy and P. Puiseux.—New researches on the liquid hydride of silicon, Si_2H_6, by MM. H. Moissan and S. Smiles. The vapour density of this liquid silicon hydride has been determined at 100° C. by Gay Lussac's method, and has been found to be 2·37. The formula Si_2H_6 requires 2·14. The compound is not decomposed on heating to 100° C.; it is very soluble in ethyl silicate, but is only slightly soluble in water. The compound possesses very strong reducing properties, acting instantly on solutions of mercury perchloride, silver nitrate and gold chloride. The most remarkable property of this new hydride is its action on saturated compounds rich in chlorine or fluorine. An attempt to determine its solubility in carbon tetrachloride gave rise to a violent explosion immediately the two liquids came into contact, and the very stable sulphur hexafluoride gave rise to a similar reaction with detonation.—On some new properties of amorphous silicon, by MM. H. Moissan and S. Smiles. When liquid silicon hydride is decomposed by a series of electric sparks, amorphous silicon is obtained in a new form. It differs from the amorphous silicon prepared by the method of Vigouroux in possessing reducing properties towards potassium permanganate, sulphate of copper, mercury perchloride, and chloride of gold. These differences are attributed by the authors to the different state of division.—On appendicitis and its causes, by M. Lannelongue. A discussion of the history of appendicitis and its relations to other diseases of the intestines and peritoneum. Appendicitis is a microbial enteritis, rarely associated with a single micro-organism, several species usually being found in association.—The action of the X-rays on very small electric sparks, by M. R. Blondlot. It was discovered some years ago that the sparking distance for a given potential is increased under the influence of the X-rays; in the present paper a new action is described. Two pieces of metal are placed a small fraction of a millimetre apart, and kept at a potential difference slightly greater than that necessary to produce a spark in the absence of the X-rays. If this spark interval is now exposed to these rays, the spark becomes distinctly brighter. Suppress the X-rays, and the

spark returns to its original condition.—Signor Schiaparelli was elected a Foreign Associate in the place of the late Baron Nordenskiöld.—On a class of functional equations, by M. Ivar Fredholm.—On the integration of differential systems which are completely integrable, by M. E. Cartan.—On injection motors, by M. L. Lecornu. A thermodynamical analysis of the Diesel petroleum motor.—On the liquefaction of air, by M. Georges Claude. A description of an improved machine for the economical production of liquid air. Worked by an engine of 30 B.H.P. about 20 litres of liquid air per hour is produced, and from a second engine worked by the escaping gases about 6 B.H.P. is obtained, thus producing about 1 litre of liquid air per 1 B.H.P.—Remarks on the above paper, by M. d'Arsonval. It is pointed out that, although the theoretical possibility of the method used by M. Claude has always been conceded, the attempts of Siemens and Solvay were failures, and Linde, in fact, definitely stated that such an arrangement could not possibly work. The results obtained after two years' work are very promising.—Remarks by M. Cailletet on the same subject.—The precautions necessary in the use of Ruhmkorff coils in radiography, by MM. Infroit and Gaiffe. It was noticed in comparing radiographs taken by the aid of induction coils with those taken by the use of static machines that the latter were always perfectly sharp whilst the former were often wanting in clearness. This effect has been traced to the action of the magnetic field of the coil on the kathode flux of the bulb. On removing the Crookes tube to a sufficient distance from the coil, this effect was obviated.—The action of self-induction in the extreme ultra-violet portion of spark spectra, by M. Eugène Néculcéa. Details are given of the measurements with lead and zinc.—On the speed of the ions in a salt flame, by M. Georges Moreau.—On the magnetic properties of the ferro-silicons, by M. Ad. Jouve. The points of inflections on the curves given point to the existence of two definite compounds of iron and silicon in the alloys studied and no more, Fe_2Si and FeSi.—The centre of gravity of binary accords, by M. A. Guillemin.—On the double nitrites of iridium, by M. E. Leidié. The preparation and properties of the double nitrites of iridium with potassium, sodium and ammonium are described.—On the constitution of the aloins; comparison with the glucosides, by N. E. Léger. The aloins appear to belong to a new class of compounds, glucosides not split up by dilute acids.—On two new sugars extracted from manna, manneotetrose and manninotriose, by M. C. Tanret.—The action of carbon bisulphide on the polyvalent amino-alcohols, by MM. L. Maquenne and E. Roux. The polyoxyamines are attacked on warming with carbon bisulphide, giving cyclic combinations containing only a single atom of sulphur, probably oxazolines.—On the estimation of lecithin in milk, by MM. F. Bordas and Sig. de Raczkowski.—The mechanism of the synthesis of leucine, by MM. A. Vila and E. Vallée.—On the application of hot air as a method of heating non-volatile liquids in the form of spray, by M. J. Glover.—Variations in the state of refraction of the human eye according to the illumination, by M. Auguste Charpentier.—On the effects produced by the section of the semicircular canals from the point of view of their stimulation and their paralysis, by M. Louis Boutan.—On the brain of the Phascolosome, by M. Marcel A. Hérubel.—On the existence of elements corresponding to a primitive form of the sieve tubes in Gymnosperms, by M. G. Chauveaud.—On the density of sea-water, by MM. Thoulet and Chevallier.

NEW SOUTH WALES.

Linnean Society, April 30.—Mr. J. H. Maiden, president, in the chair.—The gummosis of the sugar-cane, by Mr. R. Greig Smith. From the gum of diseased stalks, *Bacterium vascularum*, Cobb, was isolated and purified. Under suitable conditions of nutrition, temperature and acidity, the bacterium produces, in the laboratory, a gum or slime which is chemically identical with the gum obtained from diseased canes. The gum is therefore not a pathological secretion of the plant, but is undoubtedly of microbic origin. For the formation of gum, saccharose or lævulose is necessary; dextrose is not so useful, and the other commonly occurring sugars and carbohydrates are useless. Of the saline nutrients, phosphate is essential, and potash can be replaced by calcium or magnesium; sodium salts act as decided poisons to the microbe. The specific characters of the bacterium are described.—On a Gyrocotyle from *Chimaera Ogilbyi*, and on Gyrocotyle in general, by Prof. W. A. Haswell, F.R.S.—Notes from the Botanic Gardens, Sydney, No. 8, by Mr. J. H. Maiden and Mr. E. Betche.—Further remarks upon the mechanism of agglutination, by Mr. R. Greig Smith, Macleay bacteriologist to the Society.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), parts ii. and iii. for 1902, contain the following memoirs communicated to the Society:—

February 8.—Lothar Heffter: On the theory of real curve-integrals. Walther Borsche: Xanthene derivatives from *p*-nitrophenol. O. Kellogg: On the theory of the integral equation $A(s, t) - A(s, t) = \mu \int_0^1 A(s, r)\,A(r, t)\,dr$.

February 22.—W. Nernst and A. Lessing: On the migration of galvanic polarisation through platinum and palladium plates. R. Straubel: Experiments on thermoelectric effects in tourmaline.

March 8.—J. O. Müller: On the minimal property of the sphere. E. Wiechert: Observations at Göttingen of the polar light. A. Schoenflies: On a fundamental theorem of the analysis of position. J. Elster: Dr. V. Cuomo's measurements of the distribution of atmospheric electricity in the open air at Capri.

May 3.—H. Ebert: Report of observations on atmospheric electricity at Munich in the year 1901–2. F. Exner: Report of observations on atmospheric electricity at the stations of the Vienna Academy.

MECHANICS OF ENGINEERING.

The Mechanics of Engineering. By Prof. A. Jay DuBois, C.E., Ph.D., Yale University. Vol. i., Kinematics, Statics, Kinetics, Statics of Rigid Bodies and of Elastic Solids. Pp. xxxiv + 634. Price 31*s*. 6*d*. Vol. ii. Stresses in Framed Structures and Designing. Pp. xxiii + 609. Price £2 2*s*. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1902.)

THIS manual forms one of a number of publications which are being prepared by professors and instructors of Yale University and issued in connection with the Bicentennial Anniversary.

Dealing first with vol. i., the first 400 pages of the book, about two-thirds of the whole, are devoted to what may be considered as the preliminary work of developing the principles of the mechanics of solids. In substance this part corresponds with the author's treatise on the "Elementary Principles of Mechanics," published in three volumes, entitled "Kinematics," "Statics" and "Kinetics." The treatment is mainly analytical, graphical methods being reserved for the later chapters, in which the practical application of the principles is dealt with, and for the second volume.

In the section dealing with the fundamental and derived units of measurement, the author rightly insists on the importance of constantly keeping in mind the dimensions of the various quantities, and of checking equations from time to time by inserting the dimensions and applying the principle of homogeneity.

The old difficulty as to the use of the same word *pound* to denote both mass and force is partially overcome by writing lb. when mass is referred to, and pound when force is meant. There is thus a distinction to the eye if not to the ear. This convention, however, is not adhered to in the latter parts of the work.

In the development of the subject the reader is constantly reminded of the very useful fact that the various directed quantities which appear are vectors, and follow the vector law. But we think it would have tended to increased clearness of view if the author had brought into greater prominence the distinction between vectors the representative lines of which have different degrees of freedom, or, as they have been named, between unlocalised vectors, vectors localised in lines, and vectors which are localised at points.

The author's fundamental definition of a vector as a directed quantity merely, with the frequent inference that any quantity which has magnitude and direction is a vector and therefore obeys the vector laws, is open to criticism. The reader will find that its application to the resolution and composition of angular displacements on pp. 58 to 60 is not very clear or convincing. Stated in this form it is liable to lead to slips like the one we notice on p. 186:—

"If a rigid body has angular acceleration about an axis through its centre of mass, the resultant is a force couple in a plane at right angles to this axis. And conversely," &c.

In the chapter on central forces the author touches on planetary motions and on harmonic motion. The latter might with advantage be treated more fully in any subsequent edition, considered from the vector point of view, and with some reference to Fourier's theorem.

In treating of friction, only the simple approximate laws of solid friction are considered. Academic calculations are made as to the action and efficiencies of machines like the wheel and axle, the different systems of pulleys, the screw, &c. Some useful lessons, not revealed in the treatise under review, would be learnt by any student who had the opportunity of putting the results of these calculations to the test by actual experiments in a laboratory.

In the chapter on impact there are some practical observations on pile driving and on the limiting pressures which may be put on pile and earth foundations.

The section on the development of principles is brought to a close by a discussion of the action of the gyroscope and spinning top, and the statement of the equations of motion of a rigid body in their general form.

In the part dealing with the practical applications of principles, the subject-matter treats mainly of questions specially interesting to the civil engineer. This is naturally to be expected, having regard to the position and qualifications of the author.

There are two short chapters relating to framed structures and bending moments, evidently curtailed in anticipation of vol. ii. Then follows an interesting discussion on masonry structures, dealing with earth and water pressures, and including the design of masonry dams and retaining walls.

The closing section of the volume, comprising about 150 pages, relates to the "Statics of Elastic Solids," and deals with the design of such details as ties, riveted joints, pins and eye-bars, shafts, beams, springs and long columns; and the first volume concludes with an application of the principle of least work to the swing bridge, the metal arch, the stone arch and the suspension bridge.

The discussion of the theory of elasticity is meagre and disappointing. The various formulæ are established without giving the reader any clear insight with regard to the assumptions made and to the consequent limitations to the practical applications of the formulæ that are obtained. Consequently there is a tendency to interpret the results of the calculations as if they had the same certainty as demonstrations in geometry, and sometimes the proof given is quite illusory. For instance, the investigations on pp. 509 to 511 on the strengths of shafts need thorough revision. The work of St. Venant in regard to the torsion of shafts of other than circular section is entirely ignored. The formula $\frac{M}{I} = \frac{f}{r}$, applicable to circular shafts only, is taken as if it were true for all forms of section, and is actually applied to square and rectangular shafts. As another example of misleading theory, we think the working of example 3, p. 491, relating to a plate girder, should be entirely recast.

In other portions of the subject the author is more happy. He applies the method of strain energy and the principle of least work to framed metal arches, in a manner readily lending itself to cases of travelling loads. He also investigates temperature stresses in the two-hinged and the continuous arch. We think he is right

in also applying the same methods and principles to stone arches and to stiffened suspension bridges, and that the results so obtained are probably more to be depended on than corresponding results by older writers based on other assumptions. However, in structures of this class, liable to be self-strained, and with important factors necessarily omitted or only roughly guessed at in any estimate of the straining actions, we should not be inclined to set the same value on the results of the calculations that the author seems to attach to them. The remarks made on p. 519, in reference to calculations for a four-leg table, probably apply largely to this case, and indicate the more appropriate attitude of mind in regard to the value to be assigned to the results.

Whilst pointing out that much of vol. i. will seem inadequate to an English engineer, we are glad to draw attention to the large number of practical examples scattered throughout its pages, and in many cases fully worked out. In fact, many students might refer to these with advantage, although they will have to look elsewhere for a more thorough discussion of the principles involved.

The second volume consists of the author's well-known treatise on "Stresses in Framed Structures," eleven editions of which have already appeared, the present revised edition being the first under the new title. Some of the subject-matter of vol. i. is repeated in vol. ii., so as to make the latter complete in itself.

Students and engineers on this side of the Atlantic who are interested in bridge building will wish to possess this volume, in which modern American practice is very fully dealt with. In developing the subject, the author gives numerous examples of the design and construction of details, worked out numerically and profusely illustrated by diagrams and drawings. Towards the end, the author quotes a standard specification for bridge work, in compliance with which he works out in detail a complete design of a typical structure, giving all the calculations, and accompanying the discussion by plates comprising a full set of working drawings.

The volume concludes wish special chapters by experts on shop drawings, office work and inspection ; on the erection of bridges ; and on lofty commercial buildings, in th construction of which steel enters largely.

SURFACE-FEEDING DUCKS.

The Natural History of the British Surface-feeding Ducks. By J. G. Millais, F.Z.S. Pp. xiv + 107. With 6 Photogravures, 41 Coloured Plates, and 25 other ..ustrations. (London : Longmans, Green and Co., 1902.) Price 6 guineas net.

THE first feeling of a reader on closing Mr. Millais's "Natural [History of the Surface-feeding Ducks" will be surprise that one individual—though naturalist, sportsman and artist in one, and blessed, as the author has been from boyhood, with exceptional opportunities—should have been able single-handed to collect direct from Nature so much new and interesting information about familiar birds.

The next will be, perhaps, a touch of regret that it should have been given to the public in a form and at a price (six guineas net) which must limit its readers to the favoured few who have broad bookshelves and substantial balances at their bankers, or who may be living within reach of rich libraries.

But the tyranny of custom has decreed that a monograph of bird or beast, if it is to take rank as a serious contribution to scientific literature, must dress up to the part, and appear in the form and type of a family Bible ; and Mr. Millais, prudently no doubt, has judged it wise not to fly in the face of the conventionalities.

The result is a richly illustrated and beautifully got-up quarto volume weighing nearly nine pounds—about as much as a couple and a half of well-fed mallard—describing the life and changes of plumage of seven species of ducks more or less common in England, with pictures and shorter notices of three others which, as rare occasional visitors, have been admitted to the list of British birds. Mr. Millais has much that is interesting to tell of the courtships and varying habits of feeding of the ducks he writes about ; of their contrivances for escaping the notice of birds of prey ; and of their every-day life.

But it is to the wonderful plumage changes during the period of the drake's "eclipse," when at a time of helplessness he assumes the inconspicuous dress of his mate, that he has more especially devoted his attention. The conclusions he has arrived at add another to the marvels which every fresh discovery in natural history has revealed.
